The specific risks of a lobectomy vary depending on the specific reason for the procedure and the general state of the patient's health; they should be discussed with the surgeon. In general, the risks for any surgery requiring a general anesthetic include reactions to medications and breathing problems. As previously mentioned, patients having part of a lung removed may have difficulty breathing and may require the use of oxygen. Excessive bleeding, wound infections, and pneumonia are possible complications of a lobectomy. The chest will hurt for some time after surgery, as the surgeon must cut through the patient's ribs to expose the lung. Patients with COPD may experience shortness of breath after surgery.

### Normal results

The outcome of lobectomies depends on the general condition of the patient's lung. This variability is related to the fact that lung tissue does not regenerate after it is removed. Therefore, removal of a large portion of the lung may require a person to need oxygen or ventilator support for the rest of his or her life. On the other hand, removal of only a small portion of the lung may result in very little change to the patient's quality of life.

## QUESTIONS TO ASK THE DOCTOR

Lobectomies are performed in a hospital by a thoracic surgeon, who is a physician who specializes in chest, heart, and lung surgery. Thoracic surgeons may further specialize in one area, such as heart surgery or lung surgery. They are board-certified through the Board of Thoracic Surgery, which is recognized by the American Board of Medical Specialties. A doctor becomes board certified by completing training in a specialty area and passing a rigorous examination.

### Morbidity and mortality rates

A small percentage of patients undergoing lung lobectomy die during or soon after the surgery. This percentage varies from about 3–6% depending on the amount of lung tissue removed. Of cancer patients with completely removable stage-1 non-small cell cancer of the lung (a disease in which malignant cancer cells form in the tissues of the lung), 50% survive five years after the procedure.

### Alternatives

#### *Lung cancer*

The treatment options for lung cancer are surgery, radiation therapy, and chemotherapy, either alone or in combination, depending on the stage of the cancer.

After the cancer is found and staged, the cancer care team discusses the treatment options with the patient. In choosing a treatment plan, the most significant factors to consider are the type of lung cancer (small cell or non-small cell) and the stage of the cancer. It is very important that the doctor order all the tests needed to determine the stage of the cancer. Other factors to consider include the patient's overall physical health; the likely side effects of the treatment; and the probability of curing the disease, extending the patient's life, or relieving his or her symptoms.

#### *Chronic obstructive pulmonary disease*

Although surgery is rarely used to treat COPD, it may be considered for people who have severe symptoms that have not improved with medication therapy. A significant number of patients with advanced COPD face a miserable existence and are at high risk of death, despite advances in medical technology. This

## QUESTIONS TO ASK THE DOCTOR

- What benefits can I expect from a lobectomy?
- What are the risks of this operation?
- What are the normal results?
- How long will my recovery take?
- Are there any alternatives to this surgery?

group includes patients who remain symptomatic despite the following:

- smoking cessation
- use of inhaled bronchodilators
- treatment with antibiotics for acute bacterial infections, and inhaled or oral corticosteroids
- use of supplemental oxygen with rest or exertion
- pulmonary rehabilitation

After the severity of the patient's airflow obstruction has been evaluated, and the foregoing interventions implemented, a pulmonary disease specialist should examine him or her, with consideration given to surgical treatment.

Surgical options for treating COPD include laser therapy or the following procedures:

- **Bullectomy.** This procedure removes the part of the lung that has been damaged by the formation of large air-filled sacs called bullae.
- **Lung volume reduction surgery.** In this procedure, the surgeon removes a portion of one or both lungs, making room for the remaining lung tissue to work more efficiently. Its use is considered experimental, although it has been used in selected patients with severe emphysema.
- **Lung transplant.** In this procedure a healthy lung from a donor who has recently died is given to a person with COPD.

## Long-term care insurance

### Definition

Long-term care (LTC) insurance provides for a person's care in cases of chronic illness or disability. Policies for LTC provide insurance coverage for times when an individual cannot independently manage the essential activities of daily living (ADLs). These are universally known as feeding, dressing, bathing, toileting, and walking, as well as moving oneself from a bed to a chair (transferring). However, disabilities are not

confined to these physical situations; they can be mental as well. The key element is that they limit the individual's ability to perform any of these functions.

### Purpose

The purpose of LTC insurance is to provide coverage for a succession of caregiving services for the elderly, the chronically ill, the disabled, or the seriously injured. This care may be provided in a skilled nursing facility (SNF); a nursing home; a mental hospital; in a person's home with a registered nurse (RN); a licensed practical nurse (LPN) or nurse's aide; or even in an assisted living facility (ALF). It is important to note the societal changes responsible for the increased need for professional services to care for our loved ones. Although today's families are smaller and a number of women are working outside the home, the majority of LTC continues to be provided by unpaid, informal caregivers—family members and friends.

In 2003, more than 24 million households in the United States included a caregiver who was 50 years of age or older. Approximately three in four unpaid caregivers were women—and one-third of them are more than 65 years old. Many caregivers, especially women, balance multiple roles by providing care for both their parents and their children. Caring for a loved one full-time can overwhelm even the most devoted family member. As a result, more caregivers than ever are turning to outside resources to help with the care of a family member.

### Demographics

In 2030, it is anticipated that people aged 65 and over will comprise 20% of the population. The United States Census Bureau is projecting that the population aged 65 and over will be 39.7 million in 2010, 53.7 million in 2020, and 70.3 million in 2030. As of 2003, at least 6.4 million people aged 65 and over require LTC; one in two people over the age of 85 require this kind of care now, and at least half of the population who are over the age of 85 will need help with ADLs.

Although the elderly rely on LTC most frequently, younger persons who have chronic illnesses, severe disabilities, or have experienced a serious injury may also benefit from having LTC insurance.

### Advantages to purchasing LTC insurance

The financial risks of illness and injury are rarely considered when one is healthy and able, but that is also when the greatest choice of products with the best flexibility in cost is available for those considering LTC insurance. Having a LTC insurance policy

KEY TERMS

**Chronic illness**—A condition that lasts a year or longer, limits activity, and may require ongoing care.

**Estate planning**—Preparation of a plan of administration and disposition of one's property before or after death, including will, trusts, gifts, and power of attorney.

**Indemnity**—Protection, as by insurance, against damage or loss.

**Long-term care (LTC)**—The type of care one may need if one can no longer perform activities of daily living (ADLs) alone, such as eating, bathing or getting dressed. It also includes the kind of care one would need with a severe cognitive impairment, such as Alzheimer's disease. Care can be received in a variety of settings, including the home, assisted living facilities, adult day care centers, or hospice facilities.

**Medicaid**—Public assistance funded through the state to individuals unable to pay for health care. Medicaid can be accessed only when all prior assets and funds are depleted.

**Medicare**—A government program, administered by the Social Security Administration, which provides financial assistance to individuals over the age of 65 for hospital and medical expenses. Medicare does not cover long-term care expenses.

**Skilled nursing facility (SNF)**—A facility equipped to handle individuals with 24-hour nursing needs, postoperative recuperation, or complex medical care demands, as well as chronically-ill individuals who can no longer live independently. These facilities must be licensed by the state in which they operate to meet standards of safety, staffing, and care procedures.

enables access to quality care and choice of care provider when the need is greatest. Purchasing a policy when a person does not need it gives them the opportunity to investigate the company's financial stability (whether it is solid and how it is rated), operating performance, insurance industry rating, and its claims ratio. Rates should be guaranteed renewable; and coverage should not be canceled because of age or a change in a person's health; nor should premiums be increased on a class-wide basis.

There are several government organizations that can be of assistance in the purchase, evaluation, and

monitoring of LTC insurance. One is the state health insurance assistance program—SHIP—that can review the policy before the actual purchase. Another excellent organization is the Health Insurance Association of America (HIAA), which protects consumers from the financial risks of injury and illness by providing affordable and flexible services that represent a choice. In the United States, HIAA focuses on managed care, and, specifically, advocates on issues such as disability income and LTC insurance.

The mission of the Health Insurance Association of America is to preserve financial security, freedom of choice, and dignity in LTC insurance. Because of its mission, HIAA seeks to:

- provide access to quality care and let a person choose where care is obtained
- eliminate out-of-pocket costs and avoid reliance on government programs for the poor
- ensure quality of life for a patient's caregivers

## Description

### *Advantages*

Having a LTC insurance policy cuts out-of-pocket costs and keeps the patient from having to rely on government assistance programs. Studies from the United States Department of Health and Human Services estimate that people with LTC insurance save between \$60,000 and \$75,000 in nursing home costs, more than \$100,000 for assisted living, and actually ensure a higher quality of life for their caregiver. By having LTC at home, spouses and other family members are able to continue working or run errands while their loved one is being care for.

People of all ages usually prefer to receive LTC in their own homes, or in homelike assisted-living facilities. More than three-quarters of older Americans in need of LTC live in their communities. Most receive no paid services. The majority of LTC is provided by unpaid, informal caregivers, such as family members and friends.

### *Government assistance*

Long-term care options can be uncoordinated and expensive for individuals, their families, and public programs. According to AARP (formerly known as American Association of Retired Persons) millions of Americans have no access to LTC services. They are caught in the trap of having too much money to qualify for government assistance, but not enough money to afford the types of services they need.

Recent changes in the United States federal tax law allow for a portion of a long-term insurance premium to be tax-deductible. The amount of the deduction increases with the insured person's age.

**Medicare** may cover a month or two of home health care after a stay in the hospital, but benefits are then usually capped. This government program, administered by the Social Security Administration, is well known for providing financial assistance to seniors 65 years of age and older and to the disabled—for medical and hospital expenses—but it does not cover LTC expenses. Medicare Supplement Insurance does not cover LTC either.

The federal/state **Medicaid** program is available, but the criteria to qualify for assistance is strict. Those who meet the guidelines for Medicaid must demonstrate financial need to receive assistance; most individuals must deplete most or all of their savings and assets before becoming eligible for any benefits. In 2006, approximately two-thirds of nursing home residents were dependent on Medicaid to finance at least some of their care. For the majority of residents, LTC insurance is cost-prohibitive. To make matters worse, preexisting conditions often prevent them from obtaining coverage for which they might qualify.

### *Personal policies*

Long-term care insurance policies are often complex. People who purchase them may not read the fine print and are later forced to cancel their policies because they do not fit their needs. Increasing rates factored into some long-term policies, known as climbing premiums, may also become prohibitively expensive. However, long-term care insurance can benefit consumers, provided that such items as affordability, coverage gaps, and timing of purchase are carefully considered.

It is advisable to check the financial stability and the claims ratio of an insurance company. Long-term insurance is a serious financial investment and should be considered a part of estate planning. A qualified, independent professional should be consulted to review the policy before purchase. The state health insurance assistance program (SHIP) is also available to answer questions.

The type of care that an individual seeks or requires is an important consideration before purchasing a policy. Currently, there is no universal standard for defining long-term care facilities. A placement that is covered under one company's policy may not be covered by another. Physicians can also play a part in denial of a placement by stating that the facility of

choice is either not adequate or too advanced for an individual's needs.

When to purchase a policy is another important consideration. Individuals with a preexisting diagnosis for a debilitating condition or illness may not be eligible for coverage. This clause is common in most insurance policies of any type. However, purchasing a policy too far in advance of an anticipated need can work against a buyer. The health care industry is currently in a state of flux, and technological advances are rapid. The benefits provided in a policy that is purchased at one point in time may not match the care available in the distant future, giving the company reason to deny benefits.

Generally, LTC insurance operates as an indemnity program for potential nursing home and home health care costs. Additionally, many policies provide coverage for adult daycare, for care delivered in an assisted living facility, and for **hospice** care. Rarely are all costs covered. Some LTC policies are pure indemnity programs, which pay the insured a daily benefit contracted for by the insured. The pure indemnity program pays the full daily benefit regardless of the amount of care that the insured receives each day.

Other LTC policies pay for covered losses, or the cost of care actually received each day, up to the selected daily benefit level. This type of policy is referred to as a pool-of-money contract.

Insurance for LTC is available either as part of a group or as individual coverage, although most policies are currently purchased by individuals. Most policies cover skilled, custodial, and intermediate LTC services. A purchaser would be wise to consider a contract that covers all of these levels.

Benefits under a LTC contract are triggered in a tax-qualified policy when an insured person becomes unable to perform a number of activities associated with normal daily living or develops a cognitive impairment that requires supervision. Non-tax-qualified policies usually offer more liberal eligibility criteria. This includes long-term benefits required due to medical necessity.

### Risks

Long-term care insurance policies can be expensive and may be restrictive in what they provide. Before purchasing the policy, persons should be certain that the cost is within their means and that the plan will meet their anticipated needs. Some policies allow policy holders to use survivor **death** benefits for health care needs. It is advisable for several different policies to be compared in detail. Policies that seem

## QUESTIONS TO ASK BEFORE PURCHASING LTC INSURANCE

- Will the policy meet my needs?
- Is the policy affordable?
- What restrictions or exemptions exist?
- Under what conditions, if any, can this plan be canceled?
- Are there any laws to protect me from insurance companies or LTC facilities that provide substandard conditions and/or services?

too inexpensive when compared against the competition should be carefully evaluated. There may be hidden clauses in the contracts that limit coverage.

### Organizations that can help consumers

The Health Insurance Association of America (HIAA) protects consumers from the financial risks of illness and injury by providing flexible and affordable products and services that embody freedom of choice, and advocates on a number of issues—including LTC insurance.

The United States Department of Health and Human Services oversees the Administration on Aging's Ombudsmen Program. Established in 1972 by the Older Americans Act, the Program operates throughout the country on behalf of aging residents. Its purpose is to investigate over 260,000 complaints annually regarding various topics, including selection and payment of LTC insurance policies. The ombudsmen advocate for residents of **nursing homes**, LTC homes, assisted living facilities, and similar adult care facilities; they have made dramatic differences in the lives of LTC residents. On behalf of individuals and groups of residents, they provide information to residents and their families about the LTC system and work to improve local, state and national level programs. Ombudsmen also provide an ongoing presence in LTC facilities, monitoring care and conditions and providing a voice for those who are unable to speak for themselves.

## Lumpectomy

### Definition

Lumpectomy is a type of surgery for breast cancer. It is considered "breast-conserving" surgery because only the malignant tumor and a surrounding margin of normal breast tissue are removed. Lymph nodes in the armpit (axilla) may also be removed. This procedure is also called lymph node dissection.

### Purpose

Lumpectomy is a surgical treatment for newly diagnosed breast cancer. It is estimated that at least 50% of women with breast cancer are good candidates for this procedure. The location, size, and type of tumor are of primary importance when considering breast cancer surgery options. The size of the breast is another factor the surgeon considers when recommending surgery. The patient's psychological outlook, as well as her lifestyle and preferences, should also be taken into account when treatment decisions are being made.

The extent and severity of a cancer is evaluated, or "staged," according to a fairly complex system. Staging considers the size of the tumor and whether the cancer has spread (metastasized) to adjacent tissues, such as the chest wall, the lymph nodes, and/or to distant parts of the body. Women with early stage breast cancers are usually better candidates for lumpectomy. In most cases, a course of radiation therapy after surgery is part of the treatment. Chemotherapy or hormone treatment may also be prescribed.

In some instances, women with later stage breast cancer may be able to have lumpectomies. Chemotherapy may be administered before surgery to decrease tumor size and the chance of metastasis in selected cases.

### Contraindications to lumpectomy

There are a number of factors that may prevent or prohibit a breast cancer patient from having a lumpectomy. The tumor itself may be too large or located in an area where it would be difficult to remove with good cosmetic results. Sometimes several areas of cancer are found in one breast, so the tumor cannot be removed as a single lump. A cancer that has already attached itself to nearby structures, such as the skin or the chest wall, needs more extensive surgery.

Certain medical or physical circumstances may also eliminate lumpectomy as a treatment option. Sometimes lumpectomy may be attempted, but the surgeon is unable to remove the tumor with a sufficient amount of surrounding normal tissue. This may

During a lumpectomy, a small incision is made around the area of the lump (A). The skin is pulled back, and the tumor removed (B). The incision is closed (C). (Illustration by GGS Information Services. Cengage Learning, Gale.)

be termed “persistently positive margins,” or “lack of clear margins.” Lumpectomy is suitable for women who have had previous lumpectomies and have a recurrence of breast cancer.

Because of the need for radiation therapy after lumpectomy, this surgery may be medically unacceptable. A

breast cancer discovered during pregnancy is not amenable to lumpectomy because radiation therapy is part of the treatment. Radiation therapy cannot be administered to pregnant women because it may injure the fetus. If, however, delivery would be completed prior to the need for radiation, pregnant women may undergo lumpectomy. A woman who has already had therapeutic

## KEY TERMS

**Axillary lymph node**—Lymph nodes under the arm.

**Lymph node**—A small mass of tissue in the form of a knot or protuberance. They are the primary source of lymph fluid, which serves in the body's defense by removing toxic fluids and bacteria.

**Quadrantectomy**—Removal of a quadrant, or about a quarter of the breast.

radiation to the chest area for other reasons cannot undergo additional exposure for breast cancer therapy.

The need for radiation therapy may also be a barrier due to nonmedical concerns. Some women simply fear this type of treatment and choose more extensive surgery so that radiation will not be required. The commitment of time, usually five days a week for six weeks, may not be acceptable for others. This may be due to financial, personal, or job-related constraints. Finally, in geographically isolated areas, a course of radiation therapy may require lengthy travel and perhaps unacceptable amounts of time away from family and other responsibilities.

## Demographics

The American Cancer Society estimated that in 2007, 240,510 new cases of breast cancer would be diagnosed in the United States and 40,460 women would die as a result of the disease. Approximately one in eight women will develop breast cancer at some point in her life. The risk of developing breast cancer increases with age: women aged 30 to 40 have a one in 252 chance of developing breast cancer; women aged 40 to 50 have a one in 68 chance; women aged 50 to 60 have a one in 35 chance; and women aged 60 to 70 have a one in 27 chance—and these statistics do not even account for genetic and environmental factors.

## Description

Any amount of tissue, from 1–50% of the breast, may be removed and called a lumpectomy. Breast conservation surgery is a frequently used synonym for lumpectomy. Partial **mastectomy**, **quadrantectomy**, segmental excision, wide excision, and tylectomy are other, less commonly used names for this procedure.

The surgery is usually done while the patient is under general anesthetic. Local anesthetic with additional sedation may be used for some patients. The

tumor and surrounding margin of tissue is removed and sent to a pathologist for examination. The surgical site is then closed. Newer techniques may use **magnetic resonance imaging** guidance to more accurately identify the breast tissue to be removed. Additionally, laser instruments may be used to perform the actual lumpectomy.

If axillary lymph nodes were not removed before, a second incision may be made in the armpit. The fat pad that contains lymph nodes is removed from this area and is also sent to the pathologist for analysis. This portion of the procedure is called an axillary lymph node dissection; it is critical for determining the stage of the cancer. Typically, 10 to 15 nodes are removed, but the number may vary. A newer alternative to axillary lymph node dissection involves removal of only one lymph node. This technique, called sentinel node biopsy, samples just the first lymph node to which the breast tissue drains. If the sentinel node is negative, it is likely that no cancer has spread to more distant lymph nodes. If the sentinel node is positive, then the surgeon may have to proceed with an axillary lymph node dissection. Surgical drains may be left in place in either location to prevent fluid accumulation. The surgery may last from one to three hours.

## Diagnosis/Preparation

Routine preoperative preparations, such as having nothing to eat or drink the night before surgery, are typically ordered for a lumpectomy. Information about expected outcomes and potential complications is also part of preparation for lumpectomy, as it is for any surgical procedure. It is especially important that women know about sensations they might experience after the operation, so the they are not misinterpreted as signs of further cancer or poor healing.

If the tumor is not able to be felt (not palpable), a pre-operative localization procedure is needed. A fine wire, or other device, is placed at the tumor site, using x ray or **ultrasound** for guidance. This is usually done in the radiology department of a hospital. The woman is most often sitting up and awake, although some sedation may be administered.

## Aftercare

The patient may stay in the hospital one or two days, or return home the same day. This generally depends on the extent of the surgery, the medical condition of the patient, and physician and patient preferences. A woman usually goes home with a small bandage. The inner part of the surgical site usually

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

Lumpectomy is usually performed by a general surgeon or surgical oncologist. Radiation therapy is administered by a radiation oncologist, and chemotherapy by a medical oncologist. The procedure is frequently done in a hospital setting (especially if lymph nodes are to be removed at the same time), but specialized outpatient facilities are sometimes preferred.

has dissolvable **stitches**. The skin may be sutured or stitched; or the skin edges may be held together with steristrips, which are special thin, clear pieces of tape.

After a lumpectomy, patients are usually cautioned against lifting anything that weighs over five pounds for several days. Other activities may be restricted (especially if the axillary lymph nodes were removed) according to individual needs. Pain is often enough to limit inappropriate motion. Women are often instructed to wear a well-fitting support bra both day and night for approximately one week after surgery.

Pain is usually well controlled with prescribed medication. If it is not, the patient should contact the surgeon, as severe pain may be a sign of a complication, which needs medical attention. A return visit to the surgeon is normally scheduled approximately ten days to two weeks after the operation.

Radiation therapy is usually started as soon as possible after lumpectomy. Other additional treatments, such as chemotherapy or hormone therapy, may also be prescribed. The timing of these is specific to each individual patient.

### Risks

The risks are similar to those associated with any surgical procedure. Risks include bleeding, infection, breast asymmetry, anesthesia reaction, or unexpected scarring. A lumpectomy may also cause loss of sensation in the breast. The size and shape of the breast will be affected by the operation. Fluid can accumulate in the area where tissue was removed, requiring drainage.

If lymph node dissection is performed, there are several potential complications. A woman may experience decreased feeling in the back of her armpit. She may also experience other sensations, including numbness, tingling, or increased skin sensitivity. An

## QUESTIONS TO ASK THE DOCTOR

- Why is a lumpectomy recommended?
- What method of anesthesia/pain relief will be used?
- Will radiation or chemotherapy be administered?
- Will a lymph node dissection be performed?
- Am I a candidate for sentinel node biopsy?

inflammation of the arm vein, called phlebitis, can occur. There may be injury to the nerves controlling arm motion.

There is a risk of developing lymphedema (swelling of the arm) after axillary lymph node dissection. This swelling can range from mild to very severe. It can be treated with elastic **bandages** and specialized physical therapy, but it is a chronic condition, requiring continuing care. Lymphedema can arise at any time, even years after surgery.

### Normal results

When lumpectomy is performed, it is anticipated that it will be the definitive surgical treatment for breast cancer. Other forms of therapy, especially radiation, are often prescribed as part of the total treatment plan. The expected outcome is no recurrence of the breast cancer.

### Morbidity and mortality rates

The outcome of breast cancer is very dependent of the stage at the time of diagnosis. For stage 0 disease, the five-year survival is almost 100%. For stage I (early/lymph node negative), the five-year survival is also almost 100%. For stage II (early/lymph node positive), the five-year survival decreases to 81-92%. For stage III disease (locally advanced), the five-year survival is 54-67%. For women with stage IV (metastatic) breast cancer, the five-year survival is about 20%.

Approximately 17% of patients develop lymphedema after axillary lymph node dissection, while only 3% of patients develop lymphedema after sentinel node biopsy. Five percent of women are unhappy with the cosmetic effects of the surgery.

### Alternatives

A procedure in which the entire affected breast is removed, called a mastectomy, has been shown to be

equally effective in treating breast cancer as lumpectomy, in terms of rates of recurrence and survival. Some women may choose to have a mastectomy because they strongly fear a recurrence of breast cancer, and may consider a lumpectomy too risky. Others may feel uncomfortable with a breast that has had a cancer, and would experience more peace of mind with the entire breast removed.

## Lung biopsy

### Definition

Lung biopsy is a procedure for obtaining a small sample of lung tissue for examination. The tissue is usually examined under a microscope, and may be sent to a microbiological laboratory for culture. Microscopic examination is performed by a pathologist.

### Purpose

A lung biopsy is usually performed to determine the cause of abnormalities, such as nodules that appear on chest x rays. It can confirm a diagnosis of cancer, especially if malignant cells are detected in the

patient's sputum or bronchial washing. In addition to evaluating lung tumors and their associated symptoms, lung biopsies may be used to diagnose lung infections, especially tuberculosis and *Pneumocystis pneumonia*, drug reactions, and chronic diseases of the lungs such as sarcoidosis and pulmonary fibrosis.

A lung biopsy can be used for treatment as well as diagnosis. **Bronchoscopy**, a type of lung biopsy performed with a long, flexible slender instrument called a bronchoscope, can be used to clear a patient's air passages of secretions and to remove airway blockages.

### Demographics

Lung cancer is the leading cause of cancer-related deaths in the United States. About 213,380 patients were newly diagnosed with lung cancer in 2007 (about 114,760 in men and 98,620 in women). It is expected to claim nearly 160,390 lives in 2007 (89,510 in men and 70,880 in women). Lung cancer kills more people than cancers of the breast, prostate, colon, and pancreas combined. Cigarette smoking accounts for nearly 90% of cases of lung cancer in the United States.

### Description

#### Overview

The right and left lungs are separated by the mediastinum, which contains the heart, trachea, lymph nodes, and esophagus. Lung biopsies sometimes involve **mediastinoscopy**.

#### Types of lung biopsies

Lung biopsies are performed using a variety of techniques, depending on where the abnormal tissue is located in the lung, the health and age of the patient, and the presence of lung disease. A bronchoscopy is ordered if a lesion identified on the x ray seems to be located on the wall (periphery) of the chest. If the suspicious area lies close to the chest wall, a needle biopsy can be done. If both methods fail to diagnose the problem, an open lung biopsy may be performed. When there is a question about whether the lung cancer or suspicious mass has spread to the lymph nodes in the mediastinum, a mediastinoscopy is performed.

**BRONCHOSCOPIC BIOPSY.** During the bronchoscopy, a thin, lighted tube (bronchoscope) is passed from the nose or mouth, down the windpipe (trachea) to the air passages (bronchi) leading to the lungs. Through the bronchoscope, the physician views the airways, and is able to clear mucus from blocked airways, and collect cells or tissue samples for laboratory analysis.

## KEY TERMS

**Bronchoscopy**—A medical test that enables the physician to see the breathing passages and the lungs through a hollow, lighted tube.

**Chest x ray**—Brief exposure of the chest to radiation to produce an image of the chest and its internal structures.

**Endotracheal tube**—A hollow tube that is inserted into the windpipe to administer anesthesia.

**Lung nodule**—See pulmonary nodule.

**Lymph nodes**—Small, bean-shaped structures that serve as filters, scattered along the lymphatic vessels. Lymph nodes trap bacteria or cancer cells that are traveling through the lymphatic system.

**Malignant**—Cancerous.

**Mediastinoscopy**—A procedure that allows the physician to see the organs in the mediastinal space using a thin, lighted, hollow tube (a mediastinoscope).

**Mediastinum**—The area between the lungs, bounded by the spine, breastbone, and diaphragm.

**Pleural cavity**—The space between the lungs and the chest wall.

**Pneumothorax**—A condition in which air or gas enters the pleura (area around the lungs) and causes a collapse of the lung.

**Pulmonary nodule**—A lesion surrounded by normal lung tissue. Nodules may be caused by bacteria, fungi, or a tumor (benign or cancerous).

**Sputum**—A mucus-rich secretion that is coughed up from the passageways (bronchial tubes) and the lungs.

**Sputum cytology**—A lab test in which a microscope is used to check for cancer cells in the sputum.

**Thoracentesis**—Removal of fluid from the pleural cavity.

**NEEDLE BIOPSY.** The patient is mildly sedated, but awake during the needle biopsy procedure. He or she sits in a chair with arms folded in front on a table. An x-ray technician uses a computerized axial tomography (CAT) scanner or a fluoroscope to identify the precise location of the suspicious areas. Markers are placed on the overlying skin to identify the biopsy site. The skin is thoroughly cleansed with an antiseptic solution, and a local anesthetic is injected to numb the area. The patient will feel a brief stinging sensation when the anesthetic is injected.

The physician makes a small incision, about half an inch (1.25 cm) in length. The patient is asked to take a deep breath and hold it while the physician inserts the biopsy needle through the incision into the lung tissue to be biopsied. The patient may feel pressure, and a brief sharp pain when the needle touches the lung tissue. Most patients do not experience severe pain. The patient should refrain from coughing during the procedure. The needle is withdrawn when enough tissue has been obtained. Pressure is applied at the biopsy site and a sterile bandage is placed over the incision. A **chest x ray** is performed immediately after the procedure to check for potential complications. The entire procedure takes 30–60 minutes.

**OPEN BIOPSY.** Open biopsies are performed in a hospital **operating room** under **general anesthesia**. Once the anesthesia has taken effect, the surgeon makes an incision over the lung area, a procedure called a **thoracotomy**. Some lung tissue is removed and the incision is closed with sutures. Chest tubes are placed with one end inside the lung and the other end protruding through the closed incision. Chest tubes are used to drain fluid and blood, and re-expand the lungs. They are usually removed the day after the procedure. The entire procedure normally takes about an hour. A chest x ray is performed immediately after the procedure to check for potential complications.

**VIDEO-ASSISTED THORACOSCOPIC SURGERY.** A minimally-invasive technique, video-assisted thoracoscopic surgery (VATS) can be used to biopsy lung and mediastinal lesions. VATS may be performed on selected patients in place of open lung biopsy. While the patient is under general anesthesia, the surgeon makes several small incisions in the his or her chest wall. A thorascope, a thin, hollow, lighted tube with a tiny video camera mounted on it, is inserted through one of the small incisions. The other incisions allow the surgeon to insert special instruments to retrieve tissue for biopsy.

**MEDIASTINOSCOPY.** This procedure is performed under general anesthesia. A 2–3 inch (5–8 cm) incision is made at the base of the neck. A thin, hollow, lighted tube, called a mediastinoscope, is inserted through the incision into the space between the right and the left lungs. The surgeon removes any lymph nodes or tissues that look abnormal. The mediastinoscope is then removed, and the incision is sutured and bandaged. A mediastinoscopy takes about an hour.

## Diagnosis/Preparation

### Diagnosis

Before scheduling a lung biopsy, the physician performs a careful evaluation of the patient's medical

history and symptoms, and performs a **physical examination**. Chest x rays and sputum cytology (examination of cells obtained from a deep-cough mucus sample) are other diagnostic tests that may be performed. An **electrocardiogram** (EKG) and laboratory tests may be performed before the procedure to check for blood clotting problems, anemia, and blood type, should a **transfusion** become necessary.

### *Preparation*

During a preoperative appointment, usually scheduled within one to two weeks before the procedure, the patient receives information about what to expect during the procedure and the recovery period. During this appointment or just before the procedure, the patient usually meets with the physician (or physicians) performing the procedure (the pulmonologist, interventional radiologist, or thoracic surgeon).

A chest x ray or CAT scan of the chest is used to identify the area to be biopsied.

About an hour before the biopsy procedure, the patient receives a sedative. Medication may also be given to dry up airway secretions. General anesthesia is not used for this procedure.

For at least 12 hours before the open biopsy, VATS, or mediastinoscopy procedures, the patient should not eat or drink anything. Prior to these procedures, an intravenous line is placed in a vein in the patient's arm to deliver medications or fluids as necessary. A hollow tube, called an endotracheal tube, is passed through the patient's mouth into the airway leading to the lungs. Its purpose is to deliver the general anesthetic. The chest area is cleansed with an antiseptic solution. In the mediastinoscopy procedure, the neck is also cleansed to prepare for the incision.

### *Smoking cessation*

Patients who will undergo surgical diagnostic and treatment procedures should be encouraged to stop smoking and stop using tobacco products. The patient needs to make the commitment to be a nonsmoker after the procedure. Patients able to stop smoking several weeks before surgical procedures have fewer postoperative complications. **Smoking cessation** programs are available in many communities. The patient should ask a health care provider for more information if he or she needs help with smoking cessation.

### *Informed consent*

**Informed consent** is an educational process between health care providers and patients. Before any procedure is performed, the patient is asked to

sign a consent form. Prior to signing the form, the patient should understand the nature and purpose of the diagnostic procedure or treatment, its risks and benefits, and alternatives, including the option of not proceeding with the test or treatment. During the discussions, the health care providers are available to answer the patient's questions about the consent form or procedure.

### *Aftercare*

#### *Needle biopsy*

Following a needle biopsy, the patient is allowed to rest comfortably. He or she may be required to lie flat for two hours following the procedure to prevent the risk of bleeding. The nurse checks the patient's status at two-hour intervals. If there are no complications after four hours, the patient can go home once he or she has received instructions about resuming normal activities. The patient should rest at home for a day or two before returning to regular activities, and should avoid strenuous activities for one week after the biopsy.

#### *Open biopsy, VATS, or mediastinoscopy*

After an open biopsy, VATS, or mediastinoscopy, the patient is taken to the **recovery room** for observation. The patient receives oxygen via a face mask or nasal cannula. If no complications develop, the patient is taken to a hospital room. Temperature, blood oxygen level, pulse, blood pressure, and respiration are monitored. Chest tubes remain in place after surgery to prevent the lungs from collapsing, and to remove blood and fluids. The tubes are usually removed the day after the procedure.

The patient may experience some grogginess for a few hours after the procedure. He or she may have a sore throat from the endotracheal tube. The patient may also have some pain or discomfort at the incision site, which can be relieved by pain medication. It is common for patients to require some pain medication for up to two weeks following the procedure.

After receiving instructions about resuming normal activities and caring for the incision, the patient usually goes home the day after surgery. The patient should not drive while taking narcotic pain medication.

Patients may experience fatigue and muscle aches for a day or two because of the general anesthesia. The patient can gradually increase activities, as tolerated. Walking is recommended. Sutures are usually removed after one to two weeks.

The physician should be notified immediately if the patient experiences extreme pain, light-headedness, or difficulty breathing after the procedure. Sputum may be slightly bloody for a day or two after the procedure. Heavy or persistent bleeding requires evaluation by the physician.

### Risks

Lung biopsies should not be performed on patients who have a bleeding disorder or abnormal blood clotting because of low platelet counts, or prolonged **prothrombin time (PT)** or **partial thromboplastin time (PTT)**. Platelets are small blood cells that play a role in the blood clotting process. PT and PTT measure how well blood is clotting. If clotting times are prolonged, it may be unsafe to perform a biopsy because of the risk of bleeding. If the platelet count is lower than 50,000/cubic mm, the patient may be given a platelet transfusion as a temporary relief measure, and a biopsy can then be performed.

In addition, lung biopsies should not be performed if other tests indicate the patient has enlarged alveoli associated with emphysema, pulmonary hypertension, or enlargement of the right ventricle of the heart (cor pulmonale).

The normal risks of any surgical procedure include bleeding, infection, or pneumonia. The risk of these complications is higher in patients undergoing open biopsy procedures, as is the risk of pneumothorax (lung collapse). In rare cases, the lung collapses because of air that leaks in through the hole made by the biopsy needle. A chest x ray is done immediately after the biopsy to detect the development of this potential complication. If a pneumothorax occurs, a chest tube is inserted into the pleural cavity to re-expand the lung. Signs of pneumothorax include shortness of breath, rapid heart rate, or blueness of the skin (a late sign). If the patient has any of these symptoms after being discharged from the hospital, it is important to call the health care provider or emergency services immediately.

### *Bronchoscopic biopsy*

Bronchoscopy is generally safe, and complications are rare. If they do occur, complications may include spasms of the bronchial tubes that can impair breathing, irregular heart rhythms, or infections such as pneumonia.

### *Needle biopsy*

Needle biopsy is associated with fewer risks than open biopsy because it does not involve general

anesthesia. Some hemoptysis (coughing up blood) occurs in 5% of needle biopsies. Prolonged bleeding or infection may also occur, although these are very rare complications.

### *Open biopsy*

Possible complications of an open biopsy include infection or pneumothorax. If the patient has very severe breathing problems before the biopsy, breathing may be further impaired following the operation. Patients with normal lung function prior to the biopsy have a very small risk of respiratory problems resulting from or following the procedure.

### *Mediastinoscopy*

Complications due to mediastinoscopy are rare. Possible complications include pneumothorax or bleeding caused by damage to the blood vessels near the heart. Mediastinitis, infection of the mediastinum, may develop. Injury to the esophagus or larynx may occur. If the nerves leading to the larynx are injured, the patient may be left with a permanently hoarse voice. All of these complications are rare.

### Normal results

Normal results indicate no evidence of infection in the lungs, no detection of lumps or nodules, and cells that are free from cancerous abnormalities.

Abnormal results of needle biopsy, VATS, and open biopsy may be associated with diseases other than cancer. Nodules in the lungs may be due to active infections such as tuberculosis, or may be scars from a previous infection. In 33% of biopsies using a mediastinoscope, the biopsied lymph nodes prove to be cancerous. Abnormal results should always be considered in the context of the patient's medical history, physical examination, and other tests such as sputum examination, and chest x rays before a final diagnosis is made.

### Morbidity and mortality rates

The risk of **death** from needle biopsy is rare. The risk of death from open biopsy is one in 3,000 cases. In mediastinoscopy, death occurs in fewer than one in 3,000 cases.

### Alternatives

The type of alternative diagnostic procedures available depend upon each patient's diagnosis.

Some people may be eligible to participate in clinical trials, research programs conducted with patients

## WHO PERFORMS THIS PROCEDURE AND WHERE IS IT PERFORMED?

Fiberoptic bronchoscopy is performed by pulmonologists, physician specialists in pulmonary medicine. CAT guided needle biopsy is done by interventional radiologists, physician specialists in radiological procedures. Thoracic surgeons perform open biopsies and VATS. Specially trained nurses, x-ray, and laboratory technicians assist during the procedures and provide pre- and postoperative education and supportive care.

The procedures are performed in an operating or procedure room in a hospital.

to evaluate a new medical treatment, drug, or device. The purpose of clinical trials is to find new and improved methods of treating different diseases and special conditions. For more information on current clinical trials, visit the National Institutes of Health's ClinicalTrials.gov at <http://www.clinicaltrials.gov> or call (888) FIND-NLM [(888) 346-3656] or (301) 594-5983.

The National Cancer Institute (NCI) has conducted a clinical trial to evaluate a technology—low-dose helical computed tomography—for its effectiveness in screening for lung cancer. One study concluded that this test is more sensitive in detecting specific conditions related to lung cancer than other screening tests.

## QUESTIONS TO ASK THE DOCTOR

- Why is this procedure being performed?
- Are there any alternative options to having this procedure?
- What type of lung biopsy procedure is recommended?
- Is minimally invasive surgery an option?
- Will the patient be awake during the procedure?
- Who will be performing the procedure? How many years of experience does this physician have? How many other lung biopsies has the physician performed?
- Can medications be taken the day of the procedure?
- Can the patient have food or drink before the procedure? If not, how long before the procedure should these activities be stopped?
- How long is the hospitalization?
- After discharge, how long will it take to recover from the procedure?
- How is pain or discomfort relieved after the procedure?
- What types of symptoms should be reported to the physician?
- When can normal activities be resumed?
- When can driving be resumed?
- When can the patient return to work?
- When will the results of the procedure be given to the patient?
- How often are follow-up physician visits needed after the procedure?

## Lung transplantation

### Definition

Lung transplantation involves removal of one or both diseased lungs from a patient and the replacement of the lungs with healthy organs from a donor. Lung transplantation may refer to single, double, or even **heart-lung transplantation**.

### Purpose

The purpose of lung transplantation is to replace a lung that no longer functions with a healthy lung. To perform a lung transplantation, there should be potential for rehabilitated breathing function. Other medical treatments should be attempted before transplantation is considered. Many candidates for this procedure have end-stage fibrotic lung disease, are dependent on **oxygen therapy**, and are likely to die of their disease in 12–18 months.

### Demographics

In order to qualify for lung transplantation, a patient must suffer from severe lung disease such as:

- emphysema
- cystic fibrosis
- pulmonary fibrosis
- pulmonary hypertension
- bronchiectasis
- sarcoidosis
- silicosis

Patients with emphysema or chronic obstructive pulmonary disease (COPD) should be under 60 years

of age, have a life expectancy without transplantation of two years or less, progressive deterioration, and emotional stability in order to be considered for lung transplantation. Young patients with end-stage silicosis may be candidates for lung or heart-lung transplantation. Patients with stage III or stage IV sarcoidosis with cor pulmonale (right-sided heart failure) should be considered as early as possible for lung transplantation.

### Description

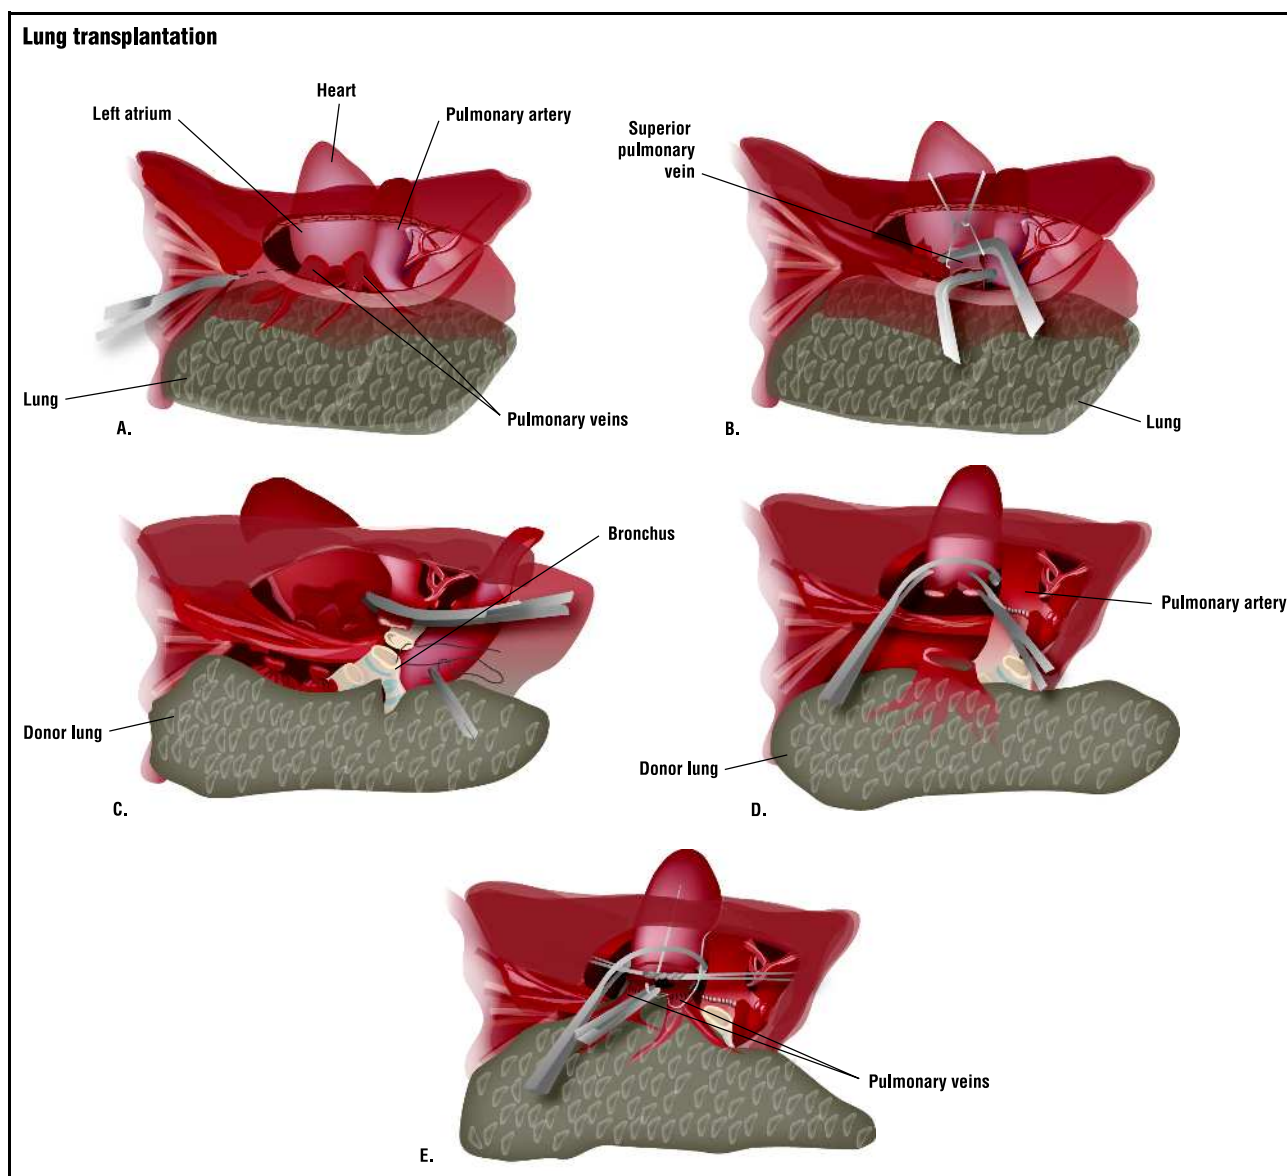

Once a patient has been selected as a possible organ recipient, the process of waiting for a donor organ match begins. The donor organ must meet specific requirements for tissue match in order to reduce the chance of organ rejection. It is estimated that it takes an average of one to two years to receive a suitable donor lung, and the wait is made less predictable by the necessity for tissue match. Patients on a recipient list must be available and ready to come to the hospital immediately when a donor match is found, since the life of the lungs outside the body is brief.

Single lung transplantation is performed via a standard **thoracotomy** (incision in the chest wall) with the patient under **general anesthesia**. Cardiopulmonary bypass (diversion of blood flow from the heart) is not always necessary for a single lung transplant. If bypass is necessary, it involves re-routing of the blood through tubes to a heart-lung bypass machine. Double lung transplantation involves implanting the lungs as two separate lungs, and cardiopulmonary bypass is usually required. The patient's lung or lungs are removed and the donor lungs are stitched into place. Drainage tubes are inserted into the chest area to help drain fluid, blood, and air out of the chest.

Heart-lung transplants always require the use of cardiopulmonary bypass. An incision is made through the middle of the sternum. The heart, lung, and supporting structures are transplanted into the recipient at the same time.

### Diagnosis/Preparation

Patients who have diseases or conditions that may make them more susceptible to organ rejection are not selected for lung transplant. This includes patients who are acutely ill and unstable; have uncontrolled or untreatable pulmonary infection; significant dysfunction of other organs, particularly the liver, kidney, or central nervous system; and those with significant coronary disease or left ventricular dysfunction. Patients who actively smoke cigarettes or are dependent on drugs or alcohol may not be selected. There are a variety of protocols that are used to determine if a

During a lung transplant, the chest is opened to reveal the heart, lungs, and major blood vessels (A). 2. Inferior and superior pulmonary veins and pulmonary artery are separated, and lung is removed (B). The bronchus of the donor lung is connected to the patient's existing bronchus (C). The pulmonary artery is attached (D), and the pulmonary vein and other blood vessels are also connected (E). (Illustration by GGS Information Services. Cengage Learning, Gale.)

patient will be placed on a transplant recipient list, and criteria may vary depending on location.

The following diagnostic tests are usually performed to evaluate a patient for lung transplantation:

- Arterial blood gases (ABG) test, which measures the amount of oxygen that the blood is able to carry to body tissues.
- Pulmonary function tests (PFTs), which measure lung volume and the rate of air flow through the lungs; the results measure the progress of the lung disease.
- Radiographic studies (x rays). The most common is the chest x ray (CXR), which takes an internal picture of the chest including the lungs, ribs, heart, and the contours of the major vessels of the chest.
- Computerized tomography (CT) scan. A chest CT scan is taken of horizontal slices of the chest to provide detailed images of the structure of the chest.
- Ventilation perfusion scan (lung scan, V/Q scan) is a test that compares right and left lung function.
- Electrocardiogram (EKG) is performed by placing electrodes on the chest and one electrode on each of

## KEY TERMS

**Anesthesia**—The loss of feeling or sensation induced by use of drugs called anesthetics.

**Bronchi**—Any of the larger air passages of the lungs.

**Bronchiectasis**—Persistent and progressive dilation of bronchi or bronchioles as a consequence of inflammatory disease such as lung infections, obstructions, tumors, or congenital abnormality.

**Bronchioles**—The tiny branches of air tubes within the lungs that are the continuation of bronchi and connect to the lung air sacs (alveoli).

**Cor pulmonale**—Enlargement of the right ventricle of the heart caused by pulmonary hypertension that may result from emphysema or bronchiectasis; eventually, the condition leads to congestive heart failure.

**Cystic fibrosis**—A generalized disorder of infants, children, and young adults characterized by widespread dysfunction of the exocrine glands, and chronic pulmonary disease due to excess mucus production in the respiratory tract.

**Emphysema**—A pathological accumulation of air in tissues or organs, especially in the lungs.

**Immunosuppressive**—Relating to the weakening or reducing of the immune system's responses to

foreign material; immunosuppressive drugs reduce the immune system's ability to reject a transplanted organ.

**Pulmonary**—Refers to the respiratory system, or breathing function and system.

**Pulmonary fibrosis**—Chronic inflammation and progressive formation of fibrous tissue in the pulmonary alveolar walls, with steadily progressive shortness of breath, resulting in death from lack of oxygen or heart failure.

**Pulmonary hypertension**—Abnormally high blood pressure within the pulmonary artery.

**Rejection**—Occurs when the body tries to attack a transplanted organ because it reacts to the organ or tissue as a foreign object and produces antibodies to destroy it. Anti-rejection (immunosuppressive) drugs help prevent rejection.

**Sarcoidosis**—A chronic disease with unknown cause that involves formation of nodules in bones, skin, lymph nodes, and lungs.

**Silicosis**—A progressive disease that results in impairment of lung function and is caused by inhalation of dust containing silica.

the four limbs. A recording of the electrical activity of the heart is obtained to provide information about the rate and rhythm of the heartbeat, and to assess any damage.

- **Echocardiogram (ECHO)** is an ultrasound of the heart, performed to evaluate the impact of lung disease on the heart. It examines the chambers, valves, aorta, and the wall motion of the heart. ECHO also provides information concerning the blood pressure in the pulmonary arteries. This information is required to plan the transplantation surgery.
- **Blood tests.** Blood samples are required for both routine and specialized testing.

In addition to tests and criteria for selection as a candidate for transplantation, patients are prepared by discussing at length the procedure, risks, and expected prognosis with the doctor. Patients should continue to follow all therapies and medications for treatment of the underlying disease, unless otherwise instructed by their physician. Since lung transplantation takes place under general anesthesia, patients are advised not to take food or drink from midnight before the surgery.

## Aftercare

Transplantation requires a long hospital stay, and recovery can last up to six months. Careful monitoring will take place in a **recovery room** immediately following the surgery and in the patient's hospital room. Patients must take immunosuppressive, or anti-rejection, drugs to reduce the risk of rejection of the transplanted organ. The body considers the new organ an invader and will fight its presence. The anti-rejection drugs lower the body's immune function in order to improve acceptance of the new organs. This also makes the patient more susceptible to infection.

Frequent check-ups, including x-ray and blood tests, will be necessary following surgery, probably for a period of several years.

## Risks

Lung transplantation is a complicated and risky procedure, partly because of the organs and systems involved, and also because of the risk of rejection by the recipient's body. Acute rejection most often occurs within the first four months following surgery, but

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

Lung transplantations are performed in a specialized organ transplantation hospital. Every transplant hospital in the United States is a member of the United Network for Organ Sharing (UNOS) and must meet specific requirements.

Lung transplantations involve specialized transplant teams usually consisting of an anesthesiologist, an infectious disease specialist, a thoracic surgeon, an ear, nose, and throat (ENT) specialist, a cardiologist, and a transplant dietician who all perform with a high level of coordination.

may occur years later. Infection is a substantial risk for organ recipients. An early complication of the surgery can be poor healing of the bronchial and tracheal openings created during the surgery. A late complication and risk is chronic rejection. This can result in inflammation of the bronchial tubes or in late infection from the prolonged use of immunosuppressive drugs to fight rejection.

### Normal results

Demonstration of normal results for lung transplantation patients include adequate lung function and improved quality of life, as well as lack of infection and rejection.

### Morbidity and mortality rates

According to the Scientific Registry of Transplant Recipients (SRTR), a total of 1,000 lung transplants were performed in the United States in 2005, although the waiting list was comprised of 3,500 people. The survival rate after single-lung transplant was more than 82% at one year, almost 60% at three years, and almost 48% at five years.

## Lymphadenectomy

### Definition

Lymphadenectomy, also called lymph node dissection, is a surgical procedure in which lymph glands are removed from the body and examined for the presence of cancerous cells. A limited or modified lymphadenectomy removes only some of the lymph nodes in the area around a tumor; a total or radical lymphadenectomy removes all of the lymph nodes in the area.

### Purpose

The lymphatic system is responsible for returning excess fluid from body tissues to the circulatory system and for defending against foreign or harmful agents such as bacteria, viruses, or cancerous cells. The major components of the lymphatic system are lymph capillaries, lymph vessels, and lymph nodes. Lymph is a clear fluid found in tissues that originates from the circulatory system. Lymph capillaries are tiny vessels that carry excess lymph to larger lymph vessels; these in turn empty to the circulatory system. Lymph nodes are small, oval- or bean-shaped masses found throughout the lymphatic system that act as filters against foreign materials. They tend to group in clusters in such areas as the neck (cervical lymph nodes), under the arm (axillary lymph nodes), the pelvis (iliac lymph nodes), and the groin (inguinal lymph nodes).

The lymphatic system plays an important role in the spread of cancerous cells throughout the body. Cancer cells can break away from their primary site of growth and travel through the bloodstream or lymphatic system to other sites in body. They may then begin growing at these distant sites or in the lymph nodes themselves; this process is called metastasis. Removal of the lymph

nodes, then, is a way that doctors can determine if a cancer has begun to metastasize. Lymphadenectomy may also be pursued as a cancer treatment to help prevent further spread of abnormal cells.

### Demographics

The American Cancer Society estimates that approximately 1,444,920 new cases of cancer were diagnosed in 2007, excluding carcinoma-in-situ and basal and squamous cell skin cancers. In 2007, 559,650 Americans are expected to die of cancer. This is 25% of all deaths within any year.

### Description

Although the specific surgical procedure may differ according to which lymph nodes are to be removed, some steps are common among all lymphadenectomies. **General anesthesia** is usually administered for the duration of surgery; this ensures that the patient remain unconscious and relaxed, and awaken with no memory of the procedure.

First, an incision is made into the skin and through the subcutaneous layers in the area where the lymph nodes are to be removed. The lymph nodes are identified and isolated. They are then carefully taken out from surrounding tissues (that is, muscles, blood vessels, and nerves). In the case of axillary node dissection, the pad of fat under the skin of the armpit is removed; generally, about 10 to 20 lymph nodes are embedded in the fat and separately removed. The incision is sutured (stitched) closed with a drain left in place to remove excess fluid from the surgical site.

Alternatively, **laparoscopy** may be used as a less invasive method of removing lymph nodes. The laparoscope is a thin, lighted tube that is inserted into the abdominal cavity through a small incision. Images taken by the laparoscope may be seen on a video monitor connected to the scope. Certain lymph nodes, such as the pelvic and aortic lymph nodes, may be removed using this technology.

### Diagnosis/Preparation

Lymph nodes may become swollen or enlarged as result of invasion by cancer cells. Swollen lymph nodes may be palpated (felt) during a physical exam. Before lymph nodes are removed, a small amount of tissue is usually removed. A biopsy will be performed on it to check for the presence of abnormal cells.

The patient will be asked to stop taking **aspirin** or aspirin-containing drugs for a period of time prior to surgery, as these can interfere with the blood’s ability to

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

Lymphadenectomy is usually performed in a hospital operating room by a surgical oncologist, a medical doctor who specializes in the surgical diagnosis and treatment of cancers.

clot. Such drugs may include prescription blood thinners (for example, Coumadin and Heparin—generically known as warfarin. However, patients should discuss their medications with regard to their upcoming surgery with their doctors, and not make any adjustments or prescription changes on their own. No food or drink after midnight the night before surgery will be allowed.

### Aftercare

Directly following surgery, the patient will be taken to the **recovery room** for constant monitoring and to recover from the effects of anesthesia. The patient may then be transferred to a regular room. If axillary nodes have been removed, the patient's arm will be elevated to help prevent postsurgical swelling. Likewise, the legs will be elevated if an inguinal lymphadenectomy had been performed. A drain placed during surgery to remove excess fluids from the surgical site will remain until the amount of fluid collected in the drain decreases significantly. The patient will generally remain in the hospital for one day.

Specific steps should be taken to minimize the risk of developing lymphedema, a condition in which excess fluid is not properly drained from body tissues, resulting in swelling. This swelling can sometimes become severe enough to interfere with daily activity. Common sites where lymphedema can develop are the arm or leg. Prior to being discharged, the patient will receive the following instructions for care of areas of the body that may be affected by lymph node removal:

- All cuts to the area should be properly cleaned, treated with an antibiotic ointment, and covered with a bandage.
- Heavy lifting should be avoided; bags should be carried on the unaffected arm.
- Tight jewelry and clothing with tight elastic bands should be avoided.
- Injections, blood draws, and blood pressure measurements should be done on the unaffected arm.
- Sunblock should be worn on the affected area to minimize the risk of sunburn.

## QUESTIONS TO ASK THE DOCTOR

- Why is lymphadenectomy recommended?
- How many lymph nodes will be removed?
- How long will the procedure take?
- When will I find out the results?
- Am I a candidate for sentinel node biopsy?
- What will happen if the results are positive for cancer?

- Steps should be taken to avoid cuts to the skin. For example, an electric razor should be used to shave the affected area; protective gloves should be worn when working with abrasive items.

### Risks

Some of the risks associated with lymphadenectomy include excessive bleeding, infection, pain, excessive swelling, vein inflammation (phlebitis), and damage to nerves during surgery. Nerve damage may be temporary or permanent and may result in weakness, numbness, tingling, and/or drooping. Lymphedema is also a risk whenever lymph nodes have been removed; it may occur immediately following surgery or from months to years later.

### Normal results

After removed lymph nodes have been examined microscopically for the presence of cancerous cells, they may be labeled node-negative (no presence of cancer cells) or node-positive (presence of cancer cells). These findings are the basis for deciding the next step in cancer treatment, if one is indicated.

### Morbidity and mortality rates

The rate of complications following lymphadenectomy depends on the specific lymph nodes being removed. For example, following axillary lymphadenectomy, there is a 17% chance of chronic lymphedema and 20% chance of abnormal skin sensations. The overall rate of complications following inguinal lymphadenectomy is approximately 15%, and 5–7% following pelvic lymphadenectomy.

### Alternatives

A technique designed to spare the unnecessary removal of normal lymph nodes is called sentinel

node biopsy. When lymph fluid moves out of a region, the sentinel lymph node is the first node it reaches. The theory behind **sentinel lymph node biopsy** is that if cancer is not present in the sentinel node, it is unlikely to have spread to other nearby nodes. This procedure may allow individuals with early stage cancers to avoid the complications associated with partial or radical removal of lymph nodes if there is little or no chance that cancer has spread to them. For example, while 17% of women have lymphedema after axillary node dissection, only 3% of women have this unpleasant complication after sentinel node biopsy.

## Magnetic resonance angiogram

### Definition

A magnetic resonance angiogram uses the equipment and technology of magnetic resonance imaging (MRI) to assess the arterial system in the body. Unlike other radiologic techniques (x rays, CT scans), magnetic resonance imaging does not involve radiation. Instead, MRI employs a combination of magnetic fields and radio waves to generate images. The magnets cause hydrogen atoms in the subject's body to line up in a particular way; the radio waves then bounce off of these aligned hydrogen atoms. This signal is captured and recorded by a computer, which uses the information to create a two- or three-dimensional image of the tissue being studied. In order to be able to adequately image the arteries during a magnetic resonance angiogram, radioactive contrast is injected in the patient. This circulates throughout the arterial system, and "lights up" the arterial system. In this way, the outline of the arteries can be visualized, and any blockages, bulges, leaks, or other abnormalities can be evaluated.

### Purpose

A magnetic resonance angiogram can be performed to assess a variety of conditions involving the arterial system throughout the body, including to

- Diagnose and monitor aneurysms
- Evaluate the extent of atherosclerosis in the coronary arteries, the carotid arteries in the neck, or in the major leg veins; may be useful prior to surgery to remove atherosclerotic plaques or to place a bypass stent
- Evaluate and monitor arteriovenous malformations, such as in the brain
- Diagnose aortic dissection

- Evaluate the arterial system that supplies the kidneys prior to kidney transplantation
- Assess the coronary arteries prior to bypass surgery
- Map out the arteries that supply a tumor prior to surgery to remove that tumor
- Evaluate any area of narrowing (stenosis) throughout the arterial system

### Description

Prior to starting the scanner for an MRA, radioactive contrast is injected through an IV in the patient's arm. The classic MRI unit consists of an examination

**Patient undergoing magnetic resonance imaging.** (PhotoSpin, Inc / Alamy)

**Doctors study MRA scans of the brain.** (Richard T. Nowitz / Phototake. Reproduced by permission.)

table on which the patient lies, and a doughnut-shaped scanner into which the table slides. During the course of the MRA, which may take between thirty minutes and two hours, the patient must lie very still, and may at times be asked to hold his or her breath. Some people are bothered by the sounds that the MRI scanner makes, which include a variety of tapping, bumping, and fan sounds. Although no one is in the room with the patient, the patient can usually communicate with the MRI technician through a two-way sound system installed within the MRI unit.

### Preparation

Because the strong magnetic field employed in MRA can interact with anything else that contains metal, it is crucial that the patient remove any jewelry, including from any piercings, prior to undergoing MRA. Other personal objects that should be removed include hearing aids, dentures, eyeglasses, hairpins. Pockets should be emptied of any metal-containing items, including coins, credit cards. Patients should inform the radiologist about any potentially metal-containing objects or medical devices that they have, such as tattooed eyeliner, a pacemaker, implanted defibrillator, aneurysm clips, cochlear implant, artificial limb, bone pin, medication patch, artificial heart valve, stent, infusion pump, or intrauterine device. People who have occupations in which they work frequently with metal should also inform the radiologist of this fact. In some cases, the MRA cannot be performed due to the presence of metal that cannot be removed and would be unsafe to expose to the magnetic fields of an MRI scanner. Sometimes, an x-ray will be ordered prior to an MRA in order to verify that there is not other metal in the body that would preclude performing the test.

## KEY TERMS

**Aneurysm**—A weakness in the wall of an artery which can cause an area of outpouching or bulging. This weakness can break, resulting in massive bleeding.

**Aortic dissection**—A situation in which a tear in the interior lining of the wall of the aorta causes bleeding between the layers of that major artery.

**Arteriovenous malformation**—An anomaly present since birth in which the arteries and veins in a particular part of the body are caught up in a complex tangle, and in which there is an abnormal pattern of blood flowing from the arteries directly into the veins.

**Atherosclerosis**—A condition in which the major arteries throughout the body become obstructed by fatty plaques, causing narrowing, obstruction of blood flow, and ultimately hardening and stiffening of the arterial walls.

Some patients with a strong history of anxiety or claustrophobia find it difficult to be enclosed in the doughnut-shaped MRI machine. There are some open machines available that may cause less anxiety. Sometimes, a sedative can be used to help the patient relax during the MRA.

Women who are pregnant or who think they may be pregnant are advised against undergoing MRA. Women who are breastfeeding and who require MRA should feed their baby with formula for two days following the procedure, and should pump and discard their breast milk, since it will be contaminated with the radioactive dye.

Most MRI units have an upper limit of weight that they can hold. Patients over 300 pounds may not be able to undergo MRI, or may need to seek an open MRI unit for their study.

### Aftercare

There is no aftercare necessary following an MRA. The patient can return to a normal diet and normal activities.

### Risks

An MRA poses very little risk to the patient. Rarely, a patient may have an allergy to the radioactive contrast utilized.

## Normal results

Normal results of an MRA would reveal normal arterial architecture, with fully patent arteries throughout the arterial tree. No narrowing, blockages, reduced blood flow, or outpouchings of the arterial walls are visualized in a normal MRA.

## Abnormal results

An MRA is abnormal if there is reduced blood flow through any part of the arterial tree. This may result in being unable to visualize an area of an artery, due to an obstruction which prevents any blood flow (and therefore any dye) from reaching that part of the arterial system. Stenosis of an artery will cause the channel of dye to appear of smaller caliber than normal. An abnormal collection of dye may accumulate in an aneurysm pocket. An aortic dissection would reveal leakage of dye between the tissue planes of the aorta. Abnormal flow of dye into the venous system may indicate the presence of an arteriovenous malformation.

## Morbidity and mortality rates

Under rare circumstances, patients may exhibit signs of allergy to the tracer.

# Magnetic resonance imaging

## Definition

Magnetic resonance imaging (MRI) is the newest, and perhaps most versatile, medical imaging technology available. Doctors can get highly refined images of the body's interior without surgery, using MRI. By using strong magnets and pulses of radio waves to manipulate the natural magnetic properties in the body, this technique makes better images of organs and soft tissues than those of other scanning technologies. MRI is particularly

**Nuclear scan of the liver and gallbladder.** (Collection CNRI / Phototake. Reproduced by permission.)

useful for imaging the brain and spine, as well as the soft tissues of joints and the interior structure of bones. The entire body is visible to the technique, which poses few known health risks.

## Purpose

MRI was developed in the 1980s. The latest additions to MRI technology are **angiography** (MRA) and spectroscopy (MRS). MRA was developed to study blood flow, while MRS can identify the chemical composition of diseased tissue and produce color images of brain function. The many advantages of MRI include:

- **Detail.** MRI creates precise images of the body based on the varying proportions of magnetic elements in different tissues. Very minor fluctuations in chemical composition can be determined. MRI images have greater natural contrast than standard x rays, computed tomography scan (CT scan), or ultrasound, all of which depend on the differing physical properties of tissues. This sensitivity lets MRI distinguish fine variations in tissues deep within the body. It also is particularly useful for spotting and distinguishing diseased tissues (tumors and other lesions) early in their development. Often, doctors prescribe an MRI scan to more fully investigate earlier findings of the other imaging techniques.
- **Scope.** The entire body can be scanned, from head to toe and from the skin to the deepest recesses of the brain. Moreover, MRI scans are not obstructed by bone, gas, or body waste, which can hinder other imaging techniques. (Although the scans can be degraded by motion such as breathing, heartbeat, and normal bowel activity.) The MRI process produces cross-sectional images of the body that are as sharp in the middle as on the edges, even of the brain through the skull. A close series of these

two-dimensional images can provide a three-dimensional view of a targeted area.

- **Safety.** MRI does not depend on potentially harmful ionizing radiation, as do standard x-ray and CT scans. There are no known risks specific to the procedure, other than for people who might have metal objects in their bodies.

MRI is being used increasingly during operations, particularly those involving very small structures in the head and neck, as well as for preoperative assessment and planning. Intraoperative MRIs have shown themselves to be safe as well as feasible, and to improve the surgeon's ability to remove the entire tumor or other abnormality.

Given all the advantages, doctors would undoubtedly prescribe MRI as frequently as **ultrasound** scanning, but the MRI process is complex and costly. The process requires large, expensive, and complicated equipment; a highly trained operator; and a doctor specializing in radiology. Generally, MRI is prescribed only when serious symptoms and/or negative results from other tests indicate a need. Many times another test is appropriate for the type of diagnosis needed.

Doctors may prescribe an MRI scan of different areas of the body.

- **Brain and head.** MRI technology was developed because of the need for brain imaging. It is one of the few imaging tools that can see through bone (the skull) and deliver high quality pictures of the brain's delicate soft tissue structures. MRI may be needed for patients with symptoms of a brain tumor, stroke, or infection (like meningitis). MRI also may be needed when cognitive and/or psychological symptoms suggest brain disease (like Alzheimer's or Huntington's diseases, or multiple sclerosis), or when developmental retardation suggests a birth defect. MRI can also provide pictures of the sinuses and other areas of the head beneath the face. Recent refinements in MRI technology may make this form of diagnostic imaging even more useful in evaluating patients with brain cancer, stroke, schizophrenia, or epilepsy. In particular, a new 3-D approach to MRI imaging known as diffusion tensor imaging, or DTI, measures the flow of water within brain tissue, allowing the radiologist to tell where the normal flow of fluid is disrupted, and to distinguish more clearly between cancerous and normal brain tissue. The introduction of DTI has led to a technique known as fiber tracking, which allows the neurosurgeon to tell whether a space-occupying brain tumor has damaged or displaced the nerve pathways in the white matter of the brain. This information in turn improves the surgeon's accuracy during the actual operation.

- **Spine.** Spinal problems can create a host of seemingly unrelated symptoms. MRI is particularly useful for identifying and evaluating degenerated or herniated spinal discs. It can also be used to determine the condition of nerve tissue within the spinal cord.
- **Joint.** MRI scanning is most commonly used to diagnose and assess joint problems. MRI can provide clear images of the bone, cartilage, ligament, and tendon that comprise a joint. MRI can be used to diagnose joint injuries due to sports, advancing age, or arthritis. MRI can also be used to diagnose shoulder problems, like a torn rotator cuff. MRI can also detect the presence of an otherwise hidden tumor or infection in a joint, and can be used to diagnose the nature of developmental joint abnormalities in children.
- **Skeleton.** The properties of MRI that allow it to see through the skull also allow it to view the inside of bones. It can be used to detect bone cancer, inspect the marrow for leukemia and other diseases, assess bone loss (osteoporosis), and examine complex fractures.
- **The rest of the body.** While CT and ultrasound satisfy most chest, abdominal, and general body imaging needs, MRI may be needed in certain circumstances to provide better pictures or when repeated scanning is required. The progress of some therapies, like liver cancer therapy, needs to be monitored, and the effect of repeated x-ray exposure is a concern.

### Precautions

MRI scanning should not be used when there is the potential for an interaction between the strong MRI magnet and metal objects that might be imbedded in a patient's body. The force of magnetic attraction on certain types of metal objects (including surgical steel) could move them within the body and cause serious injury. Metal may be imbedded in a person's body for several reasons.

- **Medical.** People with implanted cardiac pacemakers, metal aneurysm clips, or who have had broken bones repaired with metal pins, screws, rods, or plates must tell their radiologist prior to having an MRI scan. In some cases (like a metal rod in a reconstructed leg) the difficulty may be overcome.
- **Injury.** Patients must tell their doctors if they have bullet fragments or other metal pieces in their body from old wounds. The suspected presence of metal, whether from an old or recent wound, should be confirmed before scanning.
- **Occupational.** People with significant work exposure to metal particles (working with a metal grinder, for example) should discuss this with their doctor and

radiologist. The patient may need pre-scan testing—usually a single, regular x ray of the eyes to see if any metal is present.

Chemical agents designed to improve the picture and/or allow for the imaging of blood or other fluid flow during MRA may be injected. In rare cases, patients may be allergic to or intolerant of these agents, and these patients should not receive them. If these chemical agents are to be used, patients should discuss any concerns they have with their doctor and radiologist.

The potential side effects of magnetic and electric fields on human health remain a source of debate. In particular, the possible effects on an unborn baby are not well known. Any woman who is, or may be, pregnant should carefully discuss this issue with her doctor and radiologist before undergoing a scan.

As with all medical imaging techniques, obesity greatly interferes with the quality of MRI.

## Description

In essence, MRI produces a map of hydrogen distribution in the body. Hydrogen is the simplest element known, the most abundant in biological tissue, and one that can be magnetized. It will align itself within a strong magnetic field, like the needle of a compass. The earth's magnetic field is not strong enough to keep a person's hydrogen atoms pointing in the same direction, but the superconducting magnet of an MRI machine can. This comprises the “magnetic” part of MRI.

Once a patient's hydrogen atoms have been aligned in the magnet, pulses of very specific radio wave frequencies are used to knock them back out of alignment. The hydrogen atoms alternately absorb and emit radio wave energy, vibrating back and forth between their resting (magnetized) state and their agitated (radio pulse) state. This comprises the “resonance” part of MRI.

The MRI equipment records the duration, strength, and source location of the signals emitted by the atoms as they relax and translates the data into an image on a television monitor. The state of hydrogen in diseased tissue differs from healthy tissue of the same type, making MRI particularly good at identifying tumors and other lesions. In some cases, chemical agents such as gadolinium can be injected to improve the contrast between healthy and diseased tissue.

A single MRI exposure produces a two-dimensional image of a slice through the entire target area. A series of these image slices closely spaced (usually less than half an inch) makes a virtual three-dimensional view of the area.

Magnetic resonance spectroscopy (MRS) is different from MRI because MRS uses a continuous band of radio wave frequencies to excite hydrogen atoms in a variety of chemical compounds other than water. These compounds absorb and emit radio energy at characteristic frequencies, or spectra, which can be used to identify them. Generally, a color image is created by assigning a color to each distinctive spectral emission. This comprises the “spectroscopy” part of MRS. MRS is still experimental and is available in only a few research centers.

Doctors primarily use MRS to study the brain and disorders, like epilepsy, Alzheimer's disease, brain tumors, and the effects of drugs on brain growth and metabolism. The technique is also useful in evaluating metabolic disorders of the muscles and nervous system.

Magnetic resonance angiography (MRA) is another variation on standard MRI. MRA, like other types of angiography, looks specifically at fluid flow within the blood (vascular) system, but does so without the injection of dyes or radioactive tracers. Standard MRI cannot make a good picture of flowing blood, but MRA uses specific radio pulse sequences to capture usable signals. The technique is generally used in combination with MRI to obtain images that show both vascular structure and flow within the brain and head in cases of stroke, or when a blood clot or aneurysm is suspected.

Regardless of the exact type of MRI planned, or area of the body targeted, the procedure involved is basically the same and occurs in a special MRI suite. The patient lies back on a narrow table and is made as comfortable as possible. Transmitters are positioned on the body and the cushioned table that the patient is lying on moves into a long tube that houses the magnet. The tube is as long as an average adult lying down, and the tube is narrow and open at both ends. Once the area to be examined has been properly positioned, a radio pulse is applied. Then a two-dimensional image corresponding to one slice through the area is made. The table then moves a fraction of an inch and the next image is made. Each image exposure takes several seconds and the entire exam will last anywhere from 30-90 minutes. During this time, the patient is not allowed to move. If the patient moves during the scan, the picture will not be clear.

Depending on the area to be imaged, the radio-wave transmitters will be positioned in different locations.

- For the head and neck, a helmet-like hat is worn.
- For the spine, chest, and abdomen, the patient will be lying on the transmitters.
- For the knee, shoulder, or other joint, the transmitters will be applied directly to the joint.

Additional probes will monitor **vital signs** (like pulse, respiration, etc.).

The process is very noisy and confining. The patient hears a thumping sound for the duration of the procedure. Since the procedure is noisy, music supplied via earphones is often provided. Some patients get anxious or panic because they are in the small, enclosed tube. This is why vital signs are monitored and the patient and medical team can communicate between each other. If the chest or abdomen are to be imaged, the patient will be asked to hold his/her breath as each exposure is made. Other instructions may be given to the patient, as needed. In many cases, the entire examination will be performed by an MRI operator who is not a doctor. However, the supervising radiologist should be available to consult as necessary during the exam, and will view and interpret the results sometime later.

### Preparation

In some cases (such as for MRI brain scanning or an MRA), a chemical designed to increase image contrast may be given by the radiologist immediately before the exam. If a patient suffers from anxiety or claustrophobia, drugs may be given to help the patient relax.

The patient must remove all metal objects (watches, jewelry, eye glasses, hair clips, etc). Any magnetized objects (like credit and bank machine cards, audio tapes, etc.) should be kept far away from the MRI equipment because they can be erased. Patients cannot bring their wallet or keys into the MRI machine. The patient may be asked to wear clothing without metal snaps, buckles, or zippers, unless a medical gown is worn during the procedure. The patient may be asked to remove any hair spray, hair gel, or cosmetics that may interfere with the scan.

### Aftercare

No aftercare is necessary, unless the patient received medication or had a reaction to a contrast agent. Normally, patients can immediately return to their daily activities. If the exam reveals a serious condition that requires more testing and/or treatment, appropriate information and counseling will be needed.

### Risks

MRI poses no known health risks to the patient and produces no physical side effects. Again, the potential effects of MRI on an unborn baby are not well known. Any woman who is, or may be, pregnant,

## KEY TERMS

**Angiography**—Any of the different methods for investigating the condition of blood vessels, usually via a combination of radiological imaging and injections of chemical tracing and contrasting agents.

**Diffusion tensor imaging (DTI)**—A refinement of magnetic resonance imaging that allows the doctor to measure the flow of water and track the pathways of white matter in the brain. DTI is able to detect abnormalities in the brain that do not show up on standard MRI scans.

**Gadolinium**—A very rare metallic element useful for its sensitivity to electromagnetic resonance, among other things. Traces of it can be injected into the body to enhance the MRI pictures.

**Hydrogen**—The simplest, most common element known in the universe. It is composed of a single electron (negatively charged particle) circling a nucleus consisting of a single proton (positively charged particle). It is the nuclear proton of hydrogen that makes MRI possible by reacting resonantly to radio waves while aligned in a magnetic field.

**Ionizing radiation**—Electromagnetic radiation that can damage living tissue by disrupting and destroying individual cells. All types of nuclear decay radiation (including x rays) are potentially ionizing. Radio waves do not damage organic tissues they pass through.

**Magnetic field**—The three-dimensional area surrounding a magnet, in which its force is active. During MRI, the patient's body is permeated by the force field of a superconducting magnet.

**Radio waves**— Electromagnetic energy of the frequency range corresponding to that used in radio communications, usually 10,000 cycles per second to 300 billion cycles per second. Radio waves are the same as visible light, x rays, and all other types of electromagnetic radiation, but are of a higher frequency.

should carefully discuss this issue with her doctor and radiologist before undergoing a scan.

### Normal results

A normal MRI, MRA, or MRS result is one that shows the patient's physical condition to fall within normal ranges for the target area scanned.

## Abnormal results

Generally, MRI is prescribed only when serious symptoms and/or negative results from other tests indicate a need. There often exists strong evidence of a condition that the scan is designed to detect and assess. Thus, the results will often be abnormal, confirming the earlier diagnosis. At that point, further testing and appropriate medical treatment is needed. For example, if the MRI indicates the presence of a brain tumor, an MRS may be prescribed to determine the type of tumor so that aggressive treatment can begin immediately without the need for a surgical biopsy.

## Morbidity and mortality rates

Morbidity rates are excessively miniscule. The most common problems are minor bleeding and bruising at the site of contrast injection. Since neither are reportable events, morbidity can only be estimated. Occasionally, an unknown allergy to seafood is discovered after injecting contrast. No deaths have been reported from MRI tests.

## Alternatives Resources

Alternative resources include traditional x-rays and computed axial tomography (CT) scans.

## Precautions

The main precaution needed is to clean the venipuncture site with alcohol before injecting contrast. Persons with claustrophobia should be given adequate medication to sedate them.

## Side effects

The most common side effects of MRI are mild feelings of discomfort due to being enclosed during the test.

## Magnetic resonance venogram

### Definition

A magnetic resonance venogram uses the equipment and technology of magnetic resonance imaging (MRI) to assess the body's venous system. Unlike other radiologic techniques (x-rays, CT scans), magnetic resonance imaging does not involve radiation.

Instead, MRI employs a combination of magnetic fields and radio waves to generate images. The magnets cause hydrogen atoms in the subject's body to line up in a particular way; the radio waves then bounce off of these aligned hydrogen atoms. This signal is captured and recorded by a computer, which uses the information to create a two- or three-dimensional image of the tissue being studied. In order to be able to adequately image the veins during a magnetic resonance venogram, radioactive contrast is injected in the patient. This circulates throughout the venous system, and "lights up" the venous system. In this way, the outline of the veins can be visualized, and any blockages, narrowing (stenosis), leaks, or other abnormalities can be evaluated.

### Purpose

A magnetic resonance venogram can be performed to assess a variety of conditions involving the venous system throughout the body. MRV is particularly useful for the diagnosis of thrombosis (obstruction by blood clots) in the inferior vena cava (one of the very large major veins into which many of the veins in the body drain), renal (kidney) vein, and portal vein (a major vein in the liver). A thromboembolism (a blood clot that has traveled through the venous system to a point distant from its origination) in the pulmonary system can also be visualized. MRV can be used to demonstrate deep venous thrombosis anywhere in the body, such as the major leg veins or veins deep in the pelvis. Pelvic vein varicosities (enlarged, twisted, tortuous varicose veins) can also be assessed with MRV. MRV is an important method used to evaluate cerebral sinus venous thrombosis, a serious condition in which a clot blocks the drainage of blood from the brain. Lesions that occur in multiple sclerosis may also be visualized with MRV.

### Description

Prior to beginning the MRV scan, radioactive contrast is injected through an IV. The classic MRI unit consists of an examination table on which the patient lies, and a doughnut-shaped scanner into which the table slides. During the course of the MRV, which may take between thirty minutes and two hours, the patient must lie very still, and may at times be asked to hold his or her breath. Some people are bothered by the sounds that the MRI scanner makes, which include a variety of tapping, bumping, and fan sounds. Although no one is in the room with the patient, the patient can usually communicate with the MRI technician through a two-way sound system installed within the MRI unit.

## KEY TERMS

**Multiple sclerosis**—A chronic degenerative neurological disease in which demyelination of the nerves causes progressive weakness and loss of motor function.

**Thromboembolism**—A blood clot that originates in one area of the body, but travels through the venous system to another area, where it obstructs blood flow. This is particularly problematic when the thromboembolus lodges in the lung.

**Thrombus**—A blood clot that is blocking a blood vessel.

**Varicose vein**—A vein that is abnormally enlarged, swollen, and/or dilated, and may be twisted or tortuous.

### Preparation

Because the strong magnetic field employed in MRV can interact with anything else that contains metal, it is crucial that the patient remove any jewelry, including from any piercings, prior to undergoing MRV. Other personal objects that should be removed include hearing aids, dentures, eyeglasses, hairpins. Pockets should be emptied of any metal-containing items, including coins, credit cards. Patients should inform the radiologist about any potentially metal-containing objects or medical devices that they have, such as tattooed eyeliner, a pacemaker, implanted defibrillator, aneurysm clips, cochlear implant, artificial limb, bone pin, medication patch, artificial heart valve, stent, infusion pump, or intrauterine device. People who have occupations in which they work frequently with metal should also inform the radiologist of this fact. In some cases, the MRV cannot be performed due to the presence of metal that cannot be removed and would be unsafe to expose to the magnetic fields of an MRI scanner. Sometimes, an x-ray will be ordered prior to an MRV in order to verify that there is not other metal in the body that would preclude performing the test.

Some patients with a strong history of anxiety or claustrophobia find it difficult to be enclosed in the doughnut-shaped MRI machine. There are some open machines available that may cause less anxiety. Sometimes, a sedative can be used to help the patient relax during the MRV.

Women who are pregnant or who think they may be pregnant are advised against undergoing MRV.

Women who are breastfeeding and who require MRV should feed their baby with formula for two days following the procedure, and should pump and discard their breast milk, since it will be contaminated with the radioactive dye.

Most MRI units have an upper limit of weight that they can hold. Patients over 300 pounds may not be able to undergo MRI, or may need to seek an open MRI unit for their study.

### Aftercare

There is no aftercare necessary following an MRV. The patient can return to a normal diet and normal activities.

### Risks

An MRV poses very little risk to the patient. Rarely, a patient may have an allergy to the radioactive contrast utilized.

### Normal results

Normal results of an MRV would reveal normal venous architecture, with fully patent arteries throughout the venous tree. No narrowing, blockages, reduced blood flow, or outpouchings of the vein walls are visualized in a normal MRV.

### Abnormal results

An MRV is abnormal if the veins appear to be dilated, enlarged, tortuous, or if there is reduced blood flow through any part of the venous tree. If a thrombus is completely obstructing a vein, the vein may not be visualized at all, since the obstruction will prevent any blood flow (and therefore any radioactive contrast) from reaching that part of the venous system. When a thrombus is blocking a vein, the MRV may show the vein to be abnormally dilated, with a rim of increased radioactive intensity around the actual thrombus.

## Mammography

### Definition

Mammography is the study of the breast using x rays. The actual test is called a mammogram. It is an x ray of the breast which shows the fatty, fibrous, and glandular tissues. There are two types of mammograms. A screening mammogram is ordered for women who have no problems with their breasts. It consists of two x-ray views of each breast: a cranio-caudal (from above) and a mediolateral oblique (from the sides). A diagnostic mammogram is for evaluation of abnormalities in either men or women. Additional x rays from other angles, or special coned views of certain areas, are taken.

### Purpose

The purpose of screening mammography is breast cancer detection. A screening test, by definition, is used for patients without any signs or symptoms, in order to detect disease as early as possible. Many studies have shown that having regular mammograms increases a woman's chances of finding breast cancer in an early stage, when it is more likely to be curable. It has been estimated that a mammogram may find a cancer as much as two or three years before it can be felt. The American Cancer Society (ACS) guidelines recommend an annual screening mammogram for every woman of average risk beginning at age 40. Radiologists look specifically for the presence of microcalcifications and other abnormalities that can be associated with malignancy. New digital mammography and computer-aided reporting can automatically enhance and magnify the mammograms for easier identification of these tiny calcifications.

The highest risk factor for developing cancer is age. Some women are at an increased risk for developing breast cancer, such as those with a positive family history of the disease. Beginning screening mammography at a younger age may be recommended for these women.

Diagnostic mammography is used to evaluate an existing problem, such as a lump, discharge from the nipple, or unusual tenderness in one area. It is also done to evaluate further abnormalities that have been seen on screening mammograms. The radiologist normally views the films immediately and may ask for additional views such as a magnification view of one specific area. Additional studies such as an **ultrasound** of the breast may be performed as well to determine if the lesion is cystic or solid. Breast-specific **positron emission**

## KEY TERMS

**Breast biopsy**—A procedure where suspicious tissue is removed and examined by a pathologist for cancer or other disease. The breast tissue may be obtained by open surgery, or through a needle.

**Craniocaudal**—Head to tail, x-ray beam directly overhead the part being examined.

**Radiographically dense**—An abundance of glandular tissue that results in diminished anatomic detail on the mammogram.

**tomography (PET)** scans as well as an MRI (**magnetic resonance imaging**) may be ordered to further evaluate a tumor, but mammography is still the first choice in detecting small tumors on a screening basis.

## Description

A mammogram may be offered in a variety of settings. Hospitals, outpatient clinics, physician's offices, or other facilities may have mammography equipment. In the United States only places certified by the Food and Drug Administration (FDA) are legally permitted to perform, interpret, or develop mammograms. Mammograms are taken with dedicated machines using high frequency generators, low kvp, molybdenum targets and specialized x-ray beam filtration. Sensitive high contrast film and screen combinations along with prolonged developing enable the visualization of minute breast detail.

In addition to the usual paperwork, a woman will be asked to fill out a questionnaire asking for information on her current medical history. Beyond her personal and family history of cancer, details about menstruation, previous breast surgeries, child bearing, birth control, and hormone replacement therapy are recorded. Information about breast self-examination (BSE) and other breast health issues are usually available at no charge.

At some centers, a technologist may perform a **physical examination** of the breasts before the mammogram. Whether or not this is done, it is essential for the technologist to record any lumps, nipple discharge, breast pain or other concerns of the patient. All visible scars, tattoos and nipple alterations must be carefully noted as well.

Clothing from the waist up is removed, along with necklaces and dangling earrings. A hospital gown or similar covering is put on. A small self-adhesive metal

marker may be placed on each nipple by the x-ray technologist. This allows the nipple to be viewed as a reference point on the film for concise tumor location and easier centering for additional views.

Patients are positioned for mammograms differently, depending on the type of mammogram being performed:

- **Craniocaudal position (CC)**: The woman stands or sits facing the mammogram machine. One breast is exposed and raised to a level position while the height of the cassette holder is adjusted to the same level. The breast is placed mid-film with the nipple in profile and the head turned away from the side being x rayed. The shoulder is relaxed and pulled slightly backward while the breast is pulled as far forward as possible. The technologist holds the breast in place and slowly lowers the compression with a foot pedal. The breast is compressed between the film holder and a rectangle of plastic (called a paddle). The breast is compressed until the skin is taut and the breast tissue firm when touched on the lateral side. The exposure is taken immediately and the compression released. Good compression can be uncomfortable, but it is very necessary. Compression reduces the thickness of the breast, creates a uniform density and separates overlying tissues. This allows for a detailed image with a lower exposure time and decreased radiation dose to the patient. The same view is repeated on the opposite breast.
- **Mediolateral oblique position (MLO)**: The woman is positioned with her side towards the mammography unit. The film holder is angled parallel to the pectoral muscle, anywhere from 30 to 60 degrees depending on the size and height of the patient. The taller and thinner the patient the higher the angle. The height of the machine is level with the axilla (armpit). The arm is placed at the top of the cassette holder with a corner touching the armpit. The breast is lifted forward and upward and compression is applied until the breast is held firmly in place by the paddle. The nipple should be in profile and the opposite breast held away if necessary by the patient. This procedure is repeated for the other breast. A total of four x rays, two of each breast, are taken for a screening mammogram. Additional x rays, using special paddles, different breast positions, or other techniques may be taken for a diagnostic mammogram.

The mammogram may be seen and interpreted by a radiologist right away, or it may not be reviewed until later. If there is any questionable area or abnormality, extra x rays may be recommended. These may be taken during the same appointment. More commonly, especially for screening mammograms, the

woman is called back on another day for these additional films.

A screening mammogram usually takes approximately 15 to 30 minutes. A woman having a diagnostic mammogram can expect to spend up to an hour for the procedure.

The cost of mammography varies widely. Many mammography facilities accept “self referral.” This means women can schedule themselves without a physician’s referral. However, some insurance policies do require a doctor’s prescription to ensure payment. **Medicare** will pay for annual screening mammograms for all women over age 39.

## Preparation

The compression or squeezing of the breast necessary for a mammogram is a concern of many women. Mammograms should be scheduled when a woman’s breasts are least likely to be tender. One to two weeks after the first day of the menstrual period is usually best, as the breasts may be tender during a menstrual period. Some women with sensitive breasts also find that stopping or decreasing caffeine intake from coffee, tea, colas, and chocolate for a week or two before the examination decreases any discomfort. Women receiving hormone therapy may also have sensitive breasts. Over-the-counter pain relievers are recommended an hour before the mammogram appointment when pain is a significant problem.

Women should not put deodorant, powder, or lotion on their upper body on the day the mammogram is performed. Particles from these products can get on the breast or film holder and may show up as abnormalities on the mammogram. Most facilities will have special wipes available for those patients who need to wash before the mammogram.

## Aftercare

No special aftercare is required.

## Risks

The risk of radiation exposure from a mammogram is considered minimal and not significant. Experts are unanimous that any negligible risk is by far outweighed by the potential benefits of mammography. Patients who have **breast implants** must be x rayed with caution and compression is minimally applied so that the sac is not ruptured. Special techniques and positioning skills must be learned before a technologist can x ray a patient with breast implants.

Some breast cancers do not show up on mammograms, or “hide” in dense breast tissue. A normal (or negative) study is not a guarantee that a woman is cancer-free. The false-negative rate is estimated to be 15–20%, higher in younger women and women with dense breasts.

False positive readings are also possible. Breast biopsies may be recommended on the basis of a mammogram, and find no cancer. It is estimated that 75–80% of all breast biopsies resulted in benign (no cancer present) findings. This is considered an acceptable rate, because recommending fewer biopsies would result in too many missed cancers.

## Normal results

A mammography report describes details about the x-ray appearance of the breasts. It also rates the mammogram according to standardized categories, as part of the Breast Imaging Reporting and Data System (BIRADS) created by the American College of Radiology (ACR). A normal mammogram may be rated as BIRADS 1 or negative, which means no abnormalities were seen. A normal mammogram may also be rated as BIRADS 2 or benign findings. This means there are one or more abnormalities but they are clearly benign (not cancerous), or variations of normal. Some kinds of calcifications, enlarged lymph nodes or obvious cysts might generate a BIRADS 2 rating.

Many mammograms are considered borderline or indeterminate in their findings. BIRADS 3 means either additional images are needed, or an abnormality is seen and is probably (but not definitely) benign. A follow-up mammogram within a short interval of six to 12 months is suggested. This helps to ensure that the abnormality is not changing, or is “stable.” Only the affected side will be x rayed at this time. Some women are uncomfortable or anxious about waiting, and may want to consult with their doctor about having a biopsy. BIRADS 4 means suspicious for cancer. A biopsy is usually recommended in this case. BIRADS 5 means an abnormality is highly suggestive of cancer. A biopsy or other appropriate action should be taken.

Screening mammograms are not usually recommended for women under age 40 who have no special risk factors and a normal physical breast examination. A mammogram may be useful if a lump or other problem is discovered in a woman aged 30–40. Below age 30, breasts tend to be “radiographically dense,” which means the breasts contain a large amount of glandular tissue which is difficult to image in fine detail. Mammograms

for this age group are controversial. An ultrasound of the breasts is usually done instead.

### *Patient education*

The mammography technologist must be empathetic to the patient's modesty and anxiety. He or she must explain that compression is necessary to improve the quality of the image but does not harm the breasts. Patients may be very anxious when additional films are requested. Explaining that an extra view gives the radiologist more information will help to ease the patient's tension. One in eight women in North America will develop breast cancer. Educating the public on monthly breast self-examinations and yearly mammograms will help in achieving an early diagnosis and therefore a better cure.

## **Managed care plans**

### **Definition**

Managed care plans are health-care delivery systems that integrate the financing and delivery of health care. Managed care organizations generally negotiate agreements with providers to offer packaged health care benefits to covered individuals.

### **Purpose**

The purpose for managed care plans is to reduce the cost of health care services by stimulating competition and streamlining administration.

### **Description**

A majority of insured Americans belongs to a managed care plan, a health care delivery system that applies corporate business practices to medical care in order to reduce costs and streamline care. The managed care era began in the late 1980s in response to skyrocketing health-care costs, which stemmed from a number of sources. Under the fee-for-service, or indemnity, model that preceded managed care, doctors and hospitals were financially rewarded for using a multitude of expensive tests and procedures to treat patients. Other contributors to the high cost of health care were the public health advances after World War II that lengthened the average lifespan of Americans. This put increased pressure on the health-care system. In response, providers have adopted state-of-the-art diagnostic and treatment technologies as they have become available.

Managed care companies attempted to reduce costs by negotiating lower fees with clinicians and hospitals in exchange for a steady flow of patients, developing standards of treatment for specific diseases, requiring clinicians to get plan approval before hospitalizing a patient (except in the case of an emergency), and encouraging clinicians to prescribe less expensive medicines. Many plans offer financial incentives to clinicians who minimize referrals and diagnostic tests, and some even apply financial penalties, or disincentives, on those considered to have ordered unnecessary care. The primary watchdog and accreditation agency for managed care organizations is the National Committee for Quality Assurance (NCQA), a non-profit organization that also collects and disseminates health plan performance data.

Three basic types of managed care plans exist: health maintenance organizations (HMOs), preferred provider organizations (PPOs), and point-of-service (POS) plans.

- HMOs, in existence for more than 50 years, are the best known and oldest form of managed care. Participants in HMO plans must first see a primary care provider, who may be a physician or an advanced practice registered nurse (APRN), in order to be referred to a specialist. Four types of HMOs exist: the Staff Model, Group Model, Network Model, and the Independent Practice Association (IPA). The Staff

## KEY TERMS

**Health maintenance organization (HMO)**—Vertically integrated health-care provider employing many clinical professionals and usually owning or controlling a hospital.

**Preferred provider organization (PPO)**—Roster of professionals who have been approved to provide services to members of a particular managed care organization.

Model hires clinicians to work onsite. The Group Model contracts with group practice physicians on an exclusive basis. The Network Model resembles the group model except participating physicians can treat patients who are not plan members. The Independent Practice Association (IPA) contracts with physicians in private practice to see HMO patients at a prepaid rate per visit as a part of their practice.

- PPOs are more flexible than HMOs. Like HMOs, they negotiate with networks of physicians and hospitals to get discounted rates for plan members. But, unlike HMOs, PPOs allow plan members to seek care from specialists without being referred by a primary care practitioner. These plans use financial incentives to encourage members to seek medical care from providers inside the network.
- POS plans are a blend of the other types of managed care plans. They encourage plan members to seek care from providers inside the network by charging low fees for their services, but they add the option of choosing an out-of-plan provider at any time and for any reason. POS plans carry a high premium, a high deductible, or a higher co-payment for choosing an out-of-plan provider.

Several managed care theories such as those stressing continuity of care, prevention, and early intervention are applauded by health-care practitioners and patients alike. But managed care has come under fire by critics who feel patient care may be compromised by managed care cost-cutting strategies such as early hospital discharge and use of financial incentives to control referrals, which may make clinicians too cautious about sending patients to specialists. In general, the rise of managed care has shifted decision-making power away from plan members, who are limited in their choices of providers, and away from clinicians, who must concede to

managed-care administrators regarding what is considered a medically necessary procedure. Many people would like to see managed care restructured to remedy this inequitable distribution of power. Such actions would maximize consumer choice and allow health-care practitioners the freedom to provide the best care possible. According to the American Medical Association, rejection of care resulting from managed care stipulations should be subjected to an independent appeals process.

The health-care industry today is dominated by corporate values of managed care and is subject to corporate principles such as cost cutting, mergers and acquisitions, and layoffs. To thrive in such an environment, and to provide health care in accordance with professional values, health-care practitioners must educate themselves on the business of health care, including hospital operations and administrative decision making, in order to influence institutional and regional health-care policies. A sampling of the roles available for registered nurses in a managed care environment include:

- Primary care provider. The individual responsible for determining a plan of care, including referrals to specialists.
- Case manager. The person who tracks patients through the health-care system to maintain continuity of care.
- Triage nurse. In a managed care organization, these individuals help direct patients through the system by determining the urgency and level of care necessary and advising incoming patients on self-care when appropriate.
- Utilization/Resource reviewer. This individual helps manage costs by assessing the appropriateness of specialized treatments.

## Normal results

It is difficult to predict the effect of the managed care revolution on the health-care profession. All health-care providers will benefit from building broad coalitions at the state and federal levels to publicize their views on patient care issues. These coalitions will also be useful to monitor developing trends in the industry, including the impact of proposed mergers and acquisitions of health-care institutions on the provision of care.

## Mantoux test

### Definition

The Mantoux test is used to detect tuberculosis, an infectious disease caused by mycobacteria, usually *Mycobacterium tuberculosis*. Tuberculosis is a relatively common disease that usually affects the lungs, but it may also affect other organ systems and can be deadly.

### Purpose

Many people infected with TB bacteria are asymptomatic and thus have a latent TB infection. Ten percent of latent TB infections will eventually become active TB, with a greater than 50% mortality rate. The Mantoux test is used to diagnose those with a latent TB infection. Once individuals are diagnosed with latent TB infection, treatment may begin which will substantially reduce the chance that a latent TB infection progresses to disease. The detection and treatment of latent TB infection is essential in controlling and potentially eliminating tuberculosis.

### Precautions

Individuals who have been immunized for TB, have had a past cleared TB infection or are infected with a nontuberculous mycobacteria will respond to the Mantoux test similarly to those who have a latent infection, thus the Mantoux test must be interpreted with caution and if a positive result occurs, detailed history should be discussed. Recent scientific advances have led to the development of a more highly specific test for TB infection that may eventually replace the

Mantoux test as it is less likely to show a response in individuals who have been immunized for TB or infected with a nontuberculous mycobacteria.

## Description

The Mantoux test is also known as the PPD test. PPD stands for Purified Protein Derivative. PPD is an antigen that is taken from dead tuberculosis bacteria. The test is administered by using .1 ml or 5 Tuberculin units of PPD. The solution is injected into the skin of the underside of the forearm with a small needle. A small raised bump forms where the solution is administered and the health care professional should mark two edges of the raised bump to mark the injection site. The bacteria that causes tuberculosis produces a delayed hypersensitivity reaction. Within 48-72 hours after the administration of the test, an individual who has been exposed to the bacteria usually reacts to the PPD antigen in the skin of the injection area. The reaction will cause a raised hardened area or induration, at the site of the injection. The size of this area is measured and the measurement of the induration together with the patient's risk factors will determine if the result is considered positive.

## Preparation

In preparation for the test, it is important to remember that the results of the test need to be read by the healthcare provider 48-72 hours after the test is administered. The follow-up visit to have the test read should be planned before having the test administered. The healthcare provider should be notified if any surgeries or medical procedures are planned after the test or if a patient has allergies, is pregnant or breastfeeding. Lastly, the test should be postponed if the patient has a skin rash or sunburn on the underside of the forearms.

## Aftercare

It is important not to scratch, rub or press on the injection site, nor should one use ointments, lotions or sunscreen on the site, until after the test results have been read by the healthcare provider.

## Risks

Some people who are infected with tuberculosis may not have a reaction to the PPD test. This is called a false-negative result. Conversely, some people who are not infected with Mycobacterium Tuberculosis may have a positive PPD test result. This is called a false-positive result. For these reasons, the patient's medical history needs to be carefully taken into account for proper test result interpretation.

## Results

Typically a negative reaction, where there is no induration present, or the induration measurement is below the cut-off for the particular patient's risk category, would indicate that the patient does not have a latent TB infection. There are different cut-offs for the measurement of an induration for different groups of people. If an induration is present and is greater than or equal to 5 mm, this result would be considered positive in individuals who are HIV positive or who are immunosuppressed for other reasons, have had recent contact with people who have TB, or those who have had a chest x-ray that shows changes consistent with TB. If an induration is present and is greater than or equal to 10mm, this result is considered positive in patients who are recent immigrants from areas where TB has a high incidence, IV drug users, individuals who live or work in high-risk settings, have medical conditions that place them at high risk or children under the age of four. If an induration is present and is greater than or equal to 15mm, this is considered positive for any individual, even those with no known risk factors.

## Mastectomy

### Definition

Mastectomy is the surgical removal of the breast for the treatment or prevention of breast cancer.

### Purpose

Mastectomy is performed as a surgical treatment for breast cancer. The severity of a breast cancer is evaluated according to a complex system called staging. This takes into account the size of the tumor and whether it has spread to the lymph nodes, adjacent tissues, and/or distant parts of the body. A mastectomy usually is the recommended surgery for more advanced breast cancers. Women with earlier stage breast cancers, who might also have breast-conserving surgery (**lumpectomy**), may choose to have a mastectomy. In the United States, approximately 50,000 women a year undergo mastectomy.

The size, location, and type of tumor are important considerations when choosing the best surgery to treat breast cancer. The size of the breast also is an important factor. A woman's psychological concerns and lifestyle choices also should be considered when making a decision.

There are many factors that may make a mastectomy the treatment of choice for a patient. Large tumors are difficult to remove with good cosmetic results. This is especially true if the woman has small breasts. Sometimes multiple areas of cancer are found in one breast, making removal of the whole breast necessary. The surgeon sometimes is unable to remove the tumor with a sufficient amount, or margin, of normal tissue surrounding it. In this situation, the entire breast needs to be removed. Recurrence of breast cancer after a lumpectomy is another indication for mastectomy.

Radiation therapy is almost always recommended following a lumpectomy. If a woman is unable to have radiation, a mastectomy is the treatment of choice. Pregnant women cannot have radiation therapy for fear of harming the fetus. A woman with certain collagen vascular diseases, such as systemic lupus erythematosus or scleroderma, would experience unacceptable scarring and damage to her connective tissue from radiation exposure. Any woman who has had therapeutic radiation to the chest area for other reasons cannot tolerate additional exposure for breast cancer therapy.

The need for radiation therapy after breast conserving surgery may make mastectomy more appealing

for nonmedical reasons. Some women fear radiation and choose the more extensive surgery so radiation treatment will not be required. The commitment of time, usually five days a week for six weeks, may not be acceptable for other women. This may be due to financial, personal, or job-related factors. In geographically isolated areas, a course of radiation therapy may require lengthy travel and perhaps unacceptable amounts of time away from family or other responsibilities.

Some women choose mastectomy because they strongly fear recurrence of the breast cancer, and lumpectomy seems too risky. Keeping a breast that has contained cancer may feel uncomfortable for some patients. They prefer mastectomy, so the entire breast will be removed. However, studies have shown that survival rates for women choosing mastectomy and those undergoing breast-conserving surgery have been the same.

The issue of prophylactic or preventive mastectomy, or removal of the breast to prevent future breast cancer, is controversial. Women with a strong family history of breast cancer and/or who test positive for a known cancer-causing gene may choose to have both breasts removed. Patients who have had certain types of breast cancers that are more likely to recur may elect to have the unaffected breast removed. Although there is some evidence that this procedure can decrease the chances of developing breast cancer, it is not a guarantee. It is not possible to guarantee that all breast tissue has been removed. There have been cases of breast cancers occurring after both breasts have been removed.

Studies have shown that women who choose preventive mastectomy generally are satisfied with their choice, but also believe they lacked enough information before deciding, particularly about the surgery, genetic testing, and **breast reconstruction**. A recent study of women who underwent radical mastectomy of one breast and chose surgical removal of the other breast as a preventive measure reported that 83% were highly satisfied with their decision.

### Precautions

The decision to have mastectomy or lumpectomy should be carefully considered. It is important that the woman be fully informed of all the potential risks and benefits of each surgical treatment before making a choice.

## Description

There are several types of mastectomies. The radical mastectomy, also called the Halsted mastectomy, is rarely performed today. It was developed in the late 1800s, when it was thought that more extensive surgery was most likely to cure cancer. A radical mastectomy involves removal of the breast, all surrounding lymph nodes up to the collarbone, and the underlying chest muscle. Women often were left disfigured and disabled, with a large defect in the chest wall requiring **skin grafting**, and significantly decreased arm sensation and motion. Unfortunately, and inaccurately, it still is the operation many women picture when the word mastectomy is mentioned.

Surgery that removes breast tissue, nipple, an ellipse of skin, and some axillary or underarm lymph nodes, but leaves the chest muscle intact, usually is called a **modified radical mastectomy**. This is the most common type of mastectomy performed today. The surgery leaves a woman with a more normal chest shape than the older radical mastectomy procedure, and a scar that is not visible in most clothing. It also allows for immediate or delayed breast reconstruction.

In a **simple mastectomy**, only the breast tissue, nipple, and a small piece of overlying skin are removed. If a few of the axillary lymph nodes closest to the breast also are taken out, the surgery may be called an extended simple mastectomy.

There are other variations on the term mastectomy. A skin-sparing mastectomy uses special techniques that preserve the patient's breast skin for use in reconstruction, although the nipple still is removed. Total mastectomy is a confusing expression, as it may be used to refer to a modified radical mastectomy or a simple mastectomy. In 2003, surgeons reported on a new technique that spared the nipple in many women with early stage breast cancer.

Many women choose to have breast reconstruction performed in conjunction with the mastectomy. The reconstruction can be done using a woman's own abdominal tissue, or using saline-filled artificial expanders, which leave the breast relatively flat but partially reconstructed. Additionally, there are psychological benefits to coming out of the surgery with the first step to a reconstructed breast. Immediate reconstruction will add time and cost to the mastectomy procedure, but the patient can avoid the physical impact of a later surgery.

A mastectomy typically is performed in a hospital setting, but specialized outpatient facilities sometimes are used. The surgery is done under **general anesthesia**.

The type and location of the incision may vary according to plans for reconstruction or other factors, such as old scars. As much breast tissue as possible is removed. Approximately 10 to 20 axillary lymph nodes usually are removed. All tissue is sent to the pathology laboratory for analysis. If no immediate reconstruction is planned, surgical drains are left in place to prevent fluid accumulation. The skin is sutured and **bandages** are applied.

The surgery may take from two to five hours. Patients usually stay at least one night in the hospital, although outpatient mastectomy is increasingly performed for about 10% of all patients. Insurance usually covers the cost of mastectomy. If immediate reconstruction is performed, the length of stay, recovery period, insurance reimbursement, and fees will vary. In 1998, the Women's Health and Cancer Rights Act required insurance plans to cover the cost of breast reconstruction in conjunction with a mastectomy procedure.

## Preparation

Routine preoperative preparations, such as not eating or drinking the night before surgery, typically are ordered for a mastectomy. On rare occasions, the patient also may be asked to donate blood in case a blood **transfusion** is required during surgery. The patient should advise the surgeon of any medications she is taking. Information regarding expected outcomes and potential complications also should be part of preparation for a mastectomy, as for any surgical procedure. It is especially important that women know about sensations they might experience after surgery, so they are not misinterpreted as a sign of poor wound healing or recurrent cancer.

## Aftercare

In the past, women often stayed in the hospital at least several days. Now many patients go home the same day or within a day or two after their mastectomies. Visits from **home care** nurses can sometimes be arranged, but patients need to learn how to care for themselves before **discharge from the hospital**. Patients may need to learn to change bandages and/or care for the incision. The surgical drains must be attended to properly; this includes emptying the drain, measuring fluid output, moving clots through the drain, and identifying problems that need attention from the doctor or nurse. If the drain becomes blocked, fluid or blood may collect at the surgical site. Left untreated, this accumulation may cause infection and/or delayed wound healing.

After a mastectomy, activities such as driving may be restricted according to individual needs. Pain is usually well controlled with prescribed medication. Severe pain may be a sign of complications, and should be reported to the physician. A return visit to the surgeon is usually scheduled 7 to 10 days after the procedure.

Exercises to maintain shoulder and arm mobility may be prescribed as early as 24 hours after surgery. These are very important in restoring strength and promoting good circulation. However, intense **exercise** should be avoided for a time after surgery in order to prevent injury. The specific exercises suggested by the physician will change as healing progresses. Physical therapy is an integral part of care after a mastectomy, aiding in the overall recovery process.

Emotional care is another important aspect of recovery from a mastectomy. A mastectomy patient may feel a range of emotions including depression, negative self-image, grief, fear and anxiety about possible recurrence of the cancer, anger, or guilt. Patients are advised to seek counseling and/or support groups and to express their emotions to others, whether family, friends, or therapists. Assistance in dealing with the psychological effects of the breast cancer diagnosis, as well as the surgery, can be invaluable for women.

Measures to prevent injury or infection to the affected arm should be taken, especially if axillary lymph nodes were removed. There are a number of specific instructions directed toward avoiding pressure or constriction of the arm. Extra care must be exercised to avoid injury, to treat it properly if it occurs, and to seek medical attention promptly when appropriate.

Additional treatment for breast cancer may be necessary after a mastectomy. Depending on the type of tumor, lymph node status, and other factors, chemotherapy, radiation therapy, and/or hormone therapy may be prescribed.

### Risks

Risks that are common to any surgical procedure include bleeding, infection, anesthesia reaction, or unexpected scarring. After mastectomy and axillary lymph node dissection, a number of complications are possible. A woman may experience decreased feeling in the back of her armpit or other sensations including numbness, tingling, or increased skin sensitivity. Some women report phantom breast symptoms, experiencing itching, aching, or other sensations in the breast that has been removed. There may be scarring around where the lymph nodes were removed, resulting in

## KEY TERMS

**Axillary**—Located in or near the armpit.

**Lymphedema**—Swelling caused by an accumulation of fluid from faulty lymph drainage.

**Mastectomy, modified radical**—Total mastectomy with axillary lymph node dissection, but with preservation of the pectoral muscles.

**Mastectomy, radical**—Removal of the breast, pectoral muscles, axillary lymph nodes, and associated skin and subcutaneous tissue.

**Mastectomy, simple**—Removal of only the breast tissue, nipple and a small portion of the overlying skin

decreased arm mobility and requiring more intense physical therapy.

Approximately 10% to 20% of patients develop lymphedema after axillary lymph node removal. This swelling of the arm, caused by faulty lymph drainage, can range from mild to severe. It can be treated with elevation, elastic bandages, and specialized physical therapy. Lymphedema is a chronic condition that requires continuing treatment. This complication can arise at any time, even years after surgery. A new technique called sentinel lymph node mapping and biopsy often eliminates the need for removing some or all lymph nodes by testing the first lymph node for cancer.

### Normal results

A mastectomy is performed as the definitive surgical treatment for breast cancer. The goal of the procedure is that the breast cancer is completely removed and does not recur.

### Abnormal results

An abnormal result of a mastectomy is the incomplete removal of the breast cancer or a recurrence of the cancer. Other abnormal results include long-lasting (chronic) pain or impairment that does not improve after several months of physical therapy.

### Morbidity and mortality rates

Morbidity rates are modest. The most common problems include post-operative infections, unwanted scarring and issues related to emotional adjustment. A decade ago, exposure to silicone from a ruptured implant

occasionally occurred. This has been eliminated with the use of saline-filled implants. Mortality is extremely uncommon, averaging fewer than ten deaths per year.

## Alternatives Resources

There are no alternatives to mastectomy that is medically indicated. Options do exist for post-mastectomy **reconstructive surgery**. These include the use of pads and breast forms.

L. Fleming Fallon, Jr, MD, DrPH

Mastoid tympanoplasty see **Mastoidectomy**

## Mastoidectomy

### Definition

A mastoidectomy is a surgical procedure that removes an infected portion of the mastoid bone when medicinal treatment is not effective.

### Purpose

A mastoidectomy is performed to remove infected mastoid air cells resulting from ear infections, such as mastoiditis or chronic otitis, or by inflammatory disease of the middle ear (cholesteatoma). The mastoid air cells are open spaces containing air that are located throughout the mastoid bone, the prominent bone located behind the ear that projects from the temporal bone of the skull. The air cells are connected to a cavity

(Illustration by Electronic Illustrators Group.)

in the upper part of the bone, which is in turn connected to the middle ear. Aggressive infections in the middle ear can thus sometimes spread through the mastoid bone. When **antibiotics** can't clear this infection, it may be necessary to remove the infected area by surgery. The primary goal of the surgery is to completely remove infection so as to produce an infection-free ear. Mastoidectomies are also performed sometimes to repair paralyzed facial nerves.

### Demographics

According to the American Society for Microbiology, middle ear infections increased in the United States from approximately 3 million cases in 1975 to over 9 million in 1997. Middle ear infections are now the second leading cause of office visits to physicians, and this diagnosis accounts for over 40% of all outpatient antibiotic use. Ear infections are also very common in children between the ages of six months and two years. Most children have at least one ear infection before their eighth birthday.

### Description

A mastoidectomy is performed with the patient fully asleep under **general anesthesia**. There are several

different types of mastoidectomy procedures, depending on the amount of infection present:

- **Simple (or closed) mastoidectomy.** The operation is performed through the ear or through a cut (incision) behind the ear. The surgeon opens the mastoid bone and removes the infected air cells. The eardrum is incised to drain the middle ear. Topical antibiotics are then placed in the ear.
- **Radical mastoidectomy.** The procedure removes the most bone and is usually performed for extensive spread of a cholesteatoma. The eardrum and middle ear structures may be completely removed. Usually the stapes, the "stirrup" shaped bone, is spared if possible to help preserve some hearing.
- **Modified radical mastoidectomy.** In this procedure, some middle ear bones are left in place and the eardrum is rebuilt by tympanoplasty.

After surgery, the wound is stitched up around a drainage tube and a dressing is applied.

### Diagnosis/Preparation

The treating physician gives the patient a thorough ear, nose, and throat examination and uses detailed diagnostic tests, including an audiogram and

## KEY TERMS

**Audiogram**—A test of hearing at a range of sound frequencies.

**Mastoid air cells**—Numerous small intercommunicating cavities in the mastoid process of the temporal bone that empty into the mastoid antrum.

**Mastoid antrum**—A cavity in the temporal bone of the skull, communicating with the mastoid cells and with the middle ear.

**Mastoid bone**—The prominent bone behind the ear that projects from the temporal bone of the skull.

**Mastoiditis**—An inflammation of the bone behind the ear (the mastoid bone) caused by an infection spreading from the middle ear to the cavity in the mastoid bone.

**Otitis**—Inflammation of the ear, which may be marked by pain, fever, abnormalities of hearing, hearing loss, tinnitus and vertigo.

**Tympanoplasty**—Procedure to reconstruct the tympanic membrane (eardrum) and/or middle ear bone as the result of infection or trauma.

imaging studies of the mastoid bone using x rays or **CT scans** to evaluate the patient for surgery.

The patient is prepared for surgery by shaving the hair behind the ear on the mastoid bone. Mild soap and a water solution are commonly used to cleanse the outer ear and surrounding skin.

## Aftercare

The drainage tube inserted during surgery is typically removed a day or two later.

Painkillers are usually needed for the first day or two after the operation. The patient should drink fluids freely. After the **stitches** are removed, the bulky mastoid dressing can be replaced with a smaller dressing if the ear is still draining. The patient is given antibiotics for several days.

The patient should inform the physician if any of the following symptoms occur:

- bright red blood on the dressing
- stiff neck or disorientation (These may be signs of meningitis.)
- facial paralysis, drooping mouth, or problems swallowing

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

An mastoidectomy is performed in a hospital by surgeons specialized in otolaryngology, the branch of medicine concerned with the diagnosis and treatment of disorders and diseases of the ears, nose and throat. The procedure usually takes between two and three hours. It is occasionally performed on an outpatient basis in adults but usually involves hospitalization.

## Risks

Complications do not often occur, but they may include:

- persistent ear discharge
- infections, including meningitis or brain abscesses
- hearing loss
- facial nerve injury (This is a rare complication.)
- temporary dizziness
- temporary loss of taste on the side of the tongue

## Normal results

The outcome of a mastoidectomy is a clean, healthy ear without infection. However, both a modified radical and a radical mastoidectomy usually result in less than normal hearing. After surgery, a hearing aid may be considered if the patient so chooses.

## Morbidity and mortality rates

In the United States, **death** from intracranial complications of cholesteatoma is uncommon due to earlier recognition, timely surgical intervention, and supportive antibiotic therapy. Cholesteatoma remains a relatively common cause of permanent, moderate, and conductive hearing loss.

## Alternatives

Alternatives to mastoidectomy include the use of medications and delaying surgery. However, these alternative methods carry their own risk of complications and a varying degree of success. Thus, most physicians are of the opinion that patients for whom mastoidectomy is indicated should best undergo the operation, as it provides the patient with the best chance of successful treatment and the lowest risk of complications.

## QUESTIONS TO ASK THE DOCTOR

- What are the alternatives to mastoidectomy?
- What are the risks associated with the surgery?
- How will the surgery affect hearing?
- What are the possible alternative treatments?
- How long will it take to recover from the surgery?
- How many mastoidectomies do you perform each year?

## Maze procedure for atrial fibrillation

### Definition

The Maze procedure, also known as the Cox-Maze procedure, is a surgical treatment for chronic atrial fibrillation or atrial flutter. The procedure restores the heart's normal rhythm by surgically interrupting the conduction of abnormal impulses.

### Purpose

When the heart beats too fast, blood no longer circulates effectively in the body. The Maze procedure is used to stop this abnormal beating so that the heart can begin its normal rhythm and pump more efficiently. The procedure is also intended to control heart rate and prevent blood clots and strokes.

### Demographics

The Maze procedure has been performed since 1987 and was developed by Dr. James L. Cox. The average age of patients undergoing this procedure is about 52.

The Maze procedure is used to treat chronic or paroxysmal atrial fibrillation, a type of abnormal heart rhythm in which the upper chamber of the heart quivers instead of pumping in an organized way. In general, patients usually have atrial fibrillation for about eight years before undergoing the Maze procedure. The Maze procedure may be recommended for patients who need surgical treatment for coronary artery disease or valve disease. Therefore, the Maze procedure may be performed in combination with coronary artery bypass surgery (CABG), valve repair, valve replacement, or other cardiac surgery.

The Maze procedure may be recommended for patients whose atrial fibrillation has not been successfully treated with medications or other non-surgical interventional procedures. It may also be a treatment option for patients who have a history of stroke or cardiac thrombus.

Abnormal heart rhythms are slightly more common in men than in women, and the prevalence of abnormal heart rhythms, especially atrial fibrillation, increases with age. Atrial fibrillation is relatively uncommon in people under age 20.

### Description

Elective Maze surgery is usually scheduled in advance. After arriving at the hospital, an intravenous (IV) catheter will be placed in the arm to deliver

## KEY TERMS

**Ablation**—The removal or destruction of tissue.

**Ablation therapy**—A procedure used to treat arrhythmias, especially atrial fibrillation.

**Ambulatory monitors**—Small portable electrocardiograph machines that record the heart's rhythm, and include the Holter monitor, loop recorder, and trans-telephonic transmitter.

**Anti-arrhythmic**—Medication used to treat abnormal heart rhythms.

**Anticoagulant**—A medication, also called a blood thinner, that prevents blood from clotting.

**Atria**—The right and left upper chambers of the heart.

**Cardiac catheterization**—An invasive procedure used to create x rays of the coronary arteries, heart chambers and valves.

**Cardioversion**—A procedure used to restore the heart's normal rhythm by applying a controlled electric shock to the exterior of the chest.

**Echocardiogram**—An imaging procedure used to create a picture of the heart's movement, valves and chambers.

**Electrocardiogram (ECG, EKG)**—A test that records the electrical activity of the heart using small electrode patches attached to the skin on the chest.

**Electrophysiology study (EPS)**—A test that evaluates the electrical activity within the heart.

**Head-upright tilt table test**—A test used to determine the cause of fainting spells.

**Implantable cardioverter-defibrillator (ICD)**—An electronic device that is surgically placed to constantly monitor the patient's heart rate and rhythm. If a very fast, abnormal heart rate is detected, the device delivers electrical energy to the heart to resume beating in a normal rhythm.

**Nuclear imaging**—Method of producing images by detecting radiation from different parts of the body after a radioactive tracer material is administered.

**Pacemaker**—A small electronic device implanted under the skin that sends electrical impulses to the heart to maintain a suitable heart rate and prevent slow heart rates.

**Pulmonary vein isolation**—A surgical procedure used to treat atrial fibrillation.

**Stress test**—A test used to determine how the heart responds to stress.

**Ventricles**—The lower pumping chambers of the heart; the heart has two ventricles: the right and the left.

medications and fluids. **General anesthesia** is administered to put the patient to sleep.

In most cases, a traditional incision is made down the center of the patient's chest, cuts through the breastbone (sternum), and the rib cage is retracted open to expose the heart. The patient is connected to a heart-lung bypass machine, also called a cardiopulmonary bypass pump, which takes over for the heart and lungs during the surgery. The heart-lung machine removes carbon dioxide from the blood and replaces it with oxygen. A tube is inserted into the aorta to carry the oxygenated blood from the bypass machine to the aorta for circulation to the body. The heart-lung machine allows the heart's beating to be stopped so the surgeon can operate on a still heart.

Some patients may be candidates for off-pump surgery, in which the surgery is performed without the use of a heart-lung bypass machine. This is also called beating heart surgery.

The Maze surgery may be an option for some patients. The minimally invasive technique enables

the surgeon to work on the heart through small chest holes called ports and other small incisions. Advantages of minimally invasive surgery over the traditional method include smaller incisions, a shorter hospital stay, a shorter recovery period, and lower costs.

During the procedure, precise incisions, also called lesions, are made in the right and left atria to isolate and stop the unusual electrical impulses from forming. The incisions form a maze through which the impulses can travel in one direction from the top of the heart to the bottom. When the heart heals, scar tissue forms and the abnormal electrical impulses can no longer travel through the heart.

These energy sources may be used during the procedure:

- **Radiofrequency:** A radiofrequency energy catheter is used to create the incisions or lesions in the heart.
- **Microwave:** A wand-like catheter is used to direct microwave energy to create the lesions in the heart.

- Cryotherapy (also called cryoablation): Very cold temperatures are transmitted through a probe (cryoprobe) to create the lesions.

When these energy sources are used, the procedure is called surgical pulmonary vein isolation.

## Diagnosis/Preparation

### *Diagnosis of abnormal heart rhythms*

A doctor may be able to detect an irregular heart-beat during a physical exam by taking the patient's pulse. In addition, the diagnosis may be based upon the presence of certain symptoms, including:

- palpitations (feeling of skipped heartbeats or fluttering in the chest)
- pounding in the chest
- shortness of breath
- chest discomfort
- fainting
- dizziness or feeling light-headed
- weakness, fatigue, or feeling tired

Not everyone with abnormal heart rhythms will experience symptoms, so the condition may be discovered upon examination for another medical condition.

**DIAGNOSTIC TESTS.** Tests used to diagnose an abnormal heart rhythm or determine its cause include:

- blood tests
- chest x rays
- electrocardiogram
- ambulatory monitors such as the Holter monitor, loop recorder, and trans-telephonic transmitter
- stress test
- echocardiogram
- cardiac catheterization
- electrophysiology study (EPS)
- head-upright tilt table test
- nuclear medicine test such as a MUGA scan (multiple-gated acquisition scanning)

### *Preparation*

During a preoperative appointment, usually scheduled within one to two weeks before surgery, the patient will receive information about what to expect during the surgery and the recovery period. The patient will usually meet the cardiologist, anesthesiologist, nurse clinicians, and surgeon during this appointment or just before the procedure.

Medication to thin the blood (blood thinner or anticoagulant) is usually given for at least three weeks before the procedure.

If the patient develops a cold, fever, or sore throat within a few days before the surgery, he or she should notify the surgeon's office.

From midnight before the surgery, the patient should not eat or drink anything.

The morning of the procedure, the patient should take all usual medications as prescribed, with a small sip of water, unless other instructions have been given. Patients who take diabetes medications or anticoagulants should ask their doctor for specific instructions.

The patient is usually admitted to the hospital the same day the surgery is scheduled. The patient should bring a list of current medications, allergies, and appropriate medical records upon **admission to the hospital**.

The morning of surgery, the chest area is shaved and heart monitoring begins. The patient is given general anesthesia before the procedure, so he or she will be asleep during the procedure.

The traditional Maze procedure takes about an hour to perform, while the surgical pulmonary vein isolation procedure generally takes only a few minutes to perform. However, the preparation and recovery time add a few hours to both procedures. The total time in the **operating room** for each of these procedures is about three to four hours.

## Aftercare

### *Recovery in the hospital*

The patient recovers in a surgical **intensive care unit** for one to two days after the surgery. The patient will be connected to chest and breathing tubes, a mechanical ventilator, a heart monitor, and other monitoring equipment. A urinary catheter will be in place to drain urine. The breathing tube and ventilator are usually removed about six hours after surgery, but the other tubes usually remain in place as long as the patient is in the intensive care unit.

Drugs are prescribed to control pain and to prevent unwanted blood clotting. Daily doses of **aspirin** are started within six to 24 hours after the procedure.

The patient is closely monitored during the recovery period. **Vital signs** and other parameters such as heart sounds and oxygen and carbon dioxide levels in arterial blood are checked frequently. The chest tube is checked to ensure that it is draining properly. The patient may be fed intravenously for the first day or two.

Chest physiotherapy is started after the ventilator and breathing tube are removed. The therapy includes coughing, turning frequently, and taking deep breaths. Sometimes oxygen is delivered via a mask to help loosen and clear secretions from the lungs. Other exercises will be encouraged to improve the patient's circulation and prevent complications from prolonged bed rest.

If there are no complications, the patient begins to resume a normal routine around the second day. This includes eating regular food, sitting up, and walking around a bit. Before being discharged from the hospital, the patient usually spends a few days under observation in a non-surgical unit. During this time, counseling is usually provided on eating right and starting a light **exercise** program to keep the heart healthy.

The average hospital stay after the Maze surgery is five to seven days, depending on the patient's rate of recovery.

### *Recovery at home*

**MEDICATIONS.** The doctor may prescribe antiarrhythmic medications (such as beta-blockers, digitalis, or calcium channel blockers) to prevent the abnormal heart rhythm from returning. Some patients may need to take a diuretic for four to eight weeks after surgery to reduce fluid retention that may occur after surgery. Potassium supplements may be prescribed along with the diuretic medications. Some patients may be prescribed anticoagulant medication such as warfarin and aspirin to reduce the risk of blood clots. The medications prescribed may be adjusted over time to determine the best dosage and type of medication so the abnormal heart rhythm is adequately controlled.

**INCISION AND SKIN CARE.** The incision should be kept clean and dry. When the skin is healed, the incision should be washed with soapy water. The scar should not be bumped, scratched, or otherwise disturbed. Ointments, lotions, and **dressings** should not be applied to the incision unless specific instructions have been given.

**DISCOMFORT.** While the incision scar heals, which takes one to two months, it may be sore. Itching, tightness, or numbness along the incision is common. Muscle or incision discomfort may occur in the chest during activity.

**LIFESTYLE CHANGES.** The patient needs to make several lifestyle changes after surgery, including:

- Quitting smoking. Smoking causes damage to blood vessels, increases the patient's blood pressure and heart rate, and decreases the amount of oxygen available in the blood.

- Managing weight. Maintaining a healthy weight, by watching portion sizes and exercising, is important. Being overweight increases the work of the heart.
- Participating in an exercise program. The cardiac rehabilitation exercise program is usually tailored for the patient, who will be supervised by fitness professionals.
- Making dietary changes. Patients should eat a lot of fruits, vegetables, grains, and non-fat or low-fat dairy products, and reduce fats to less than 30% of all calories.
- Taking medications as prescribed. Aspirin and other heart medications may be prescribed, and the patient may need to take these medications for life.
- Following up with health-care providers. An exercise test is often scheduled during one of the first follow-up visits to determine how effective the surgery was and to confirm that progressive exercise is safe. The patient needs to regularly see the physician for follow-up visits to monitor his or her recovery and control risk factors.

### **Risks**

The Maze procedure is major surgery and patients may experience any of the normal complications associated with major surgery and anesthesia, such as the risk of bleeding, pneumonia, or infection. The risk of stroke is 1%. One common complication that has occurred early after surgery is fluid retention. However, **diuretics** are now prescribed to reduce the risk of this complication. To date, minimal long-term adverse effects have been reported in patients undergoing the Maze procedure.

### **Normal results**

Full recovery from the Maze procedure takes six to eight weeks. Upon release from the hospital, the patient will feel weak because of the extended bed rest in the hospital. Within a few weeks, the patient should begin to feel stronger.

Most patients are able to drive in about three to four weeks, after receiving approval from their physician. Sexual activity can generally be resumed in three to four weeks, depending on the patient's rate of recovery.

It takes about six to eight weeks for the sternum to heal. During this time, the patient should not perform activities that cause pressure or put weight on the breastbone or tension on the arms and chest. Pushing and pulling heavy objects (such as mowing the lawn) should be avoided and lifting objects more than 20 lbs (9 kg) is not permitted. The patient should not hold his

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

Heart surgeons specially trained in the Maze procedure should perform this procedure. The Maze procedure takes place in an operating room in a hospital. When evaluating where to have the surgery performed, the patient should find out how many Maze procedures have been performed at that facility, how many Maze procedures are performed per month, when the surgeons at that facility started performing the procedure, and what the typical outcomes or results are for their patients.

or her arms above shoulder level for a long period of time. The patient should try not to stand in one place for longer than 15 minutes. Stair climbing is permitted unless other instructions have been given.

Within four to six weeks, people with sedentary office jobs can return to work; people with physical jobs (such as construction work or jobs requiring heavy lifting) must wait longer (up to 12 weeks).

In about 30% of all patients, atrial fibrillation will recur temporarily right after surgery. This is common. Medications are usually prescribed to control atrial fibrillation after surgery. About three months after the surgery, medications are often reduced and then stopped.

In about 7–10% of patients, a permanent pacemaker is needed as a result of the procedure or sometimes due to underlying sinus node dysfunction.

About 90–95% of patients have a return of normal heart rhythm within one year after the surgery. Among U.S. surgeons reporting their data in the January 2000 issue of *Seminars in Thoracic and Cardiovascular Surgery*, the overall success rate of the Maze procedure is from 90–98%. Some hospitals report a 98% success rate in lone atrial fibrillation patients (those who do not have any other underlying heart conditions) undergoing the traditional Maze procedure. An 80–90% success rate has been reported for the surgical pulmonary vein isolation procedure.

### Morbidity and mortality rates

The overall operative mortality for patients undergoing the Maze procedure is 3%. The mortality rate increases among patients over age 65.

## QUESTIONS TO ASK THE DOCTOR

- Am I a candidate for minimally invasive surgery?
- Am I a candidate for the “off-pump” surgery technique?
- Who will be performing the surgery? How many years of experience does this surgeon have? How many other Maze procedures has this surgeon performed?
- Can I take my medications the day of the surgery?
- Can I eat or drink the day of the surgery? If not, how long before the surgery should I stop eating or drinking?
- How long will I have to stay in the hospital after the surgery?
- After I go home from the hospital, how long will it take me to recover from surgery?
- What should I do if I experience symptoms similar to those I felt before surgery?
- What types of symptoms should I report to my doctor?
- What types of medications will I have to take after surgery?
- When will I be able to resume my normal activities, including work and driving?
- When will I find out if the surgery was successful?
- What if the surgery was not successful?
- If I have had the surgery once, can I have it again to correct future blockages?
- Will I have any pain or discomfort after the surgery? If so, how can I relieve this pain or discomfort?
- Are there any medications, foods, or activities I should avoid to prevent my symptoms from recurring?
- How often do I need to see my doctor for follow-up visits after the surgery?

Atrial fibrillation is not immediately life threatening, but it can lead to other heart rhythm problems. Follow-up data from the Framingham Heart Study and the Anti-arrhythmia Versus Implantable Defibrillators Trial have shown that atrial fibrillation is a predictor of increased mortality.

According to a 2002 study published in the *New England Journal of Medicine*, controlling a patient's heart rate is as important as controlling the patient's

heart rhythm to prevent **death** and complications from cardiovascular causes. The study also concluded that anticoagulant therapy is important to reduce the risk of stroke and is appropriate therapy in patients who have recurring, persistent atrial fibrillation even after they received treatment.

### Alternatives

Health care providers usually try to correct the heart rhythm with medication and recommend lifestyle changes and other interventional procedures such as **cardioversion** before recommending the Maze procedure.

Lifestyle changes often recommended to treat abnormal heart rhythms include:

- quitting smoking
- avoiding activities that prompt the symptoms of abnormal heart rhythms
- limiting alcohol intake
- limiting or not using caffeine, which may produce more symptoms in some people with abnormal heart rhythms
- avoiding stimulant-containing medications such as some cough and cold remedies

If the Maze procedure is not successful in restoring the normal heart rhythm, other treatments for abnormal heart rhythms include:

- permanent pacemakers
- implantable cardioverter-defibrillator
- ablation therapy

## Mechanical circulation support

### Definition

Mechanical circulatory support is used to treat patients with advanced heart failure. A mechanical pump is surgically implanted to provide pulsatile or non-pulsatile flow of blood to supplement or replace the blood flow generated by the native heart. Types of circulatory support pumps include pneumatic and electromagnetic pumps. Rotary pumps are also available.

### Purpose

Heart failure causes low cardiac output, which results in inadequate blood pressure and reduced blood flow to the brain, kidneys, heart, and/or lungs. Pharmaceutical and surgical treatments (other than transplantation) are all typically exhausted before mechanical circulatory support is initiated. The extent of failure exhibited by one or both ventricles of the heart

## KEY TERMS

**Anticoagulant**—Pharmaceutical to prevent clotting proteins and platelets in the blood to be activated to form a blood clot.

**Cannulae**—Tubes that provide access to the blood once inserted into the heart or blood vessels.

**Cardiac**—Of or relating to the heart.

**Cardiac output**—The liter per minute blood flow generated by contraction of the heart.

**Cardiopulmonary bypass**—Diversion of blood flow away from the right atrium and return of blood beyond the left ventricle to bypass the heart and lungs.

determines if univentricular or biventricular support is required. In either case, blood flow is supplemented or replaced by a mechanical circulatory support device. The device works by removing blood from the inlet of the ventricle(s) and reinjecting it at the outlet of the ventricle(s) in order to increase blood pressure and blood flow to the brain, kidneys, heart, and lungs.

Some devices, along with the intra-aortic balloon pump (IABP), centrifugal pump, and extracorporeal membrane oxygenation (ECMO), are systems that are meant to sustain the patient until the heart recovers. If recovery does not occur, or is not expected, then **heart transplantation** becomes the next desired course of treatment. In this case, intermediate- to long-term mechanical circulatory support devices are required.

### Description

Short-, intermediate-, and long-term support requires bedside monitoring of the equipment and patient throughout treatment. The specialized nature of the equipment and the intensive patient care require dedicated staff who are able to provide continuous bedside treatment.

In most instances, patients receive anticoagulants, drugs that prevent clots in the blood. Frequent laboratory testing determines the proper amount of medication required to prevent blood clots. To mimic the lining of blood vessels, some surfaces of the device attract the body's cells, which stick to the device surface and eliminate the need for anticoagulation.

Blood flow generated by these devices is able to sustain blood pressure and flow to the heart, kidneys, liver, and brain. Temporary assist devices sustain vital organ tissues in situations where recovery of the heart function is anticipated. Long-term support devices

sustain patients until a donor heart is available for transplantation.

### *Short- to intermediate-term support devices*

ECMO circulatory support provides cardiopulmonary bypass. Both cardiac and pulmonary (lung) function can be supplemented with this device. The complexity of care and the need for highly trained staff with specialized equipment limit the availability of ECMO to specialty care facilities. Surgical cannulation (placement of tubes) is required. **Postoperative care** in the critical care unit requires dedicated bedside staffing.

Blood flow to the lungs is reduced as blood is drained from the venous circulation. Blood pumped by the left ventricle is also reduced as blood is returned directly to the systemic circulation. The heart is allowed to rest, pumping less blood than needed to maintain pressure and flow to the vital organs. As cardiac function improves, flow from ECMO support is reduced, allowing the heart to gradually resume normal function. The cannulae are surgically removed from the patient once the heart can maintain adequate cardiac output. Systemic anticoagulation is required throughout the length of support, and often leads to complications of stroke and coagulopathies. Long-term use of ECMO is limited since the patient is immobilized and sedated during treatment.

Ease of insertion for placement in the aorta makes the intra-aorta balloon pump (IABP) the most often used **ventricular assist device**. Specialty care centers provide this service in the **cardiac catheterization laboratory**, **operating room**, critical care unit, and emergency room. Secondary-care-level hospitals can also employ this technology. Well-trained staff are required to monitor equipment at regular intervals and troubleshoot problems.

Left ventricular (the lower left chamber of the heart) support with the IABP reduces the workload of the heart and increases blood flow to the vital organs. The balloon inflates during diastole (the filling phase of the heart) to deliver increased oxygen-saturated blood to the heart; blood flow is also increased to the arteries. Deflation of the balloon occurs prior to systole (the emptying phase of the heart).

With recovery of the heart, the IABP device is timed to inflate with every second or third heart beat. The catheter is removed, non-surgically, when the heart can sustain blood pressure and systemic blood flow. Anticoagulation is achieved with minimal drugs throughout the treatment. The device can be in place up to several weeks, but duration is limited because the patient must be immobilized during the treatment.

Centrifugal pumps are able to provide support to one or both ventricles. Blood is removed from the left or right atrium (upper chamber) and returned to the aorta or pulmonary artery, respectively; therefore, surgery is required to place the device. Specialty care facilities have the staff and equipment to provide treatment to heart failure patients with the use of mechanical circulatory support devices. Postoperative care in critical care units requires continuous monitoring by dedicated staff.

The cannulae are passed through the chest wall to attach to a pump that draws blood into the device and propels it to the arterial cannula. As the heart recovers, blood flow is decreased from the centrifugal pump until the device can be removed. An anticoagulant drug is delivered continuously during treatment with a centrifugal pump, and patient immobilization limits the length of support to several weeks.

### *Intermediate- to long-term support devices*

When short-term support devices such as ECMO, IABP, and the centrifugal pump are ineffective to sustain the patient to recovery or organ transplantation, a medium- or long-term device is required. An advantage of treatment with a medium- to long-term device is that it allows the patient to be mobile. In some instances, patients have been able to leave the hospital for continued treatment at home with the implanted device. Complete recovery of the heart has been demonstrated in 5–15% of patients being supported as a bridge to organ transplantation.

Pulsatile paracorporeal mechanical circulatory support devices provide pulsatile support for the left or right ventricle, or both. Cannulation of the left or right atrium, along with the aorta or pulmonary artery, respectively, requires a surgical approach. The heart is emptied of blood by the assist device, so there is little ejection from the body's heart.

Removal of the device occurs at the time of cardiac transplant, unless the body's heart has healed during support. Anticoagulation is achieved by low doses of drugs. Some patients regain mobility while assisted by these devices.

### *Destination therapies*

Destination therapies intended to supplement or permanently replace the body's heart are provided by chronic implantation of the mechanical circulatory support system. For example, total artificial hearts (TAH) replace the body's heart. Upon removal of the native heart, the TAH will be attached to the major blood vessels, thereby supplying blood pressure and flow to both the pulmonary and systemic circulation. Destination therapies are currently in clinical

## QUESTIONS TO ASK THE DOCTOR

- What type of implant will I require?
- Who will be performing the surgery? How many years of experience does this surgeon have? How many other implants has this surgeon performed?
- Can I take my medications the day of the surgery?
- Can I eat or drink the day of the surgery? If not, how long before the surgery should I stop eating or drinking?
- How long will I have to stay in the hospital after the surgery?
- After I go home from the hospital, how long will it take me to recover from surgery?
- What should I do if I experience symptoms similar to those I felt before surgery?
- What types of symptoms should I report to my doctor?
- What types of medications will I have to take after surgery?
- When will I be able to resume my normal activities, including work and driving?
- When will I find out if the surgery was successful?
- What if the surgery was not successful?
- If I have had the surgery once, will the pump ever need replacement?
- Will I have any pain or discomfort after the surgery? If so, how can I relieve this pain or discomfort?
- Are there any medications, foods, or activities I should avoid to prevent my symptoms from recurring?
- How often do I need to see my doctor for follow-up visits after the surgery?

trials, offering those patients not eligible for organ transplantation a promising future.

## Preparation

General anesthetic is given to the patient if a chest incision will be used to expose the heart or if blood vessels need to be exposed. Sedation with local anesthetic is sufficient if the vessels can be accessed with a needle stick. Cardiac monitoring will be performed, including electrocardiograph and cardiovascular pressures. Blood tests prior to surgery are used to measure blood elements and electrolytes. Once all sterile

connections are complete, the physician will request that mechanical circulatory support be initiated. Adjustments may be frequent initially, but decrease as the patient stabilizes.

### Normal results

Once stable following device implant, the patient is cared for in the **intensive care unit (ICU)**. Any change in patient status is reported to the physician. Around-the-clock bedside care is provided by trained nursing staff.

These patients are very ill when they require device implant, often suffering from multi-system organ failure as a result of poor blood flow. The long-term survival is superior at one year when compared to medical treatment alone. Patients that continue to improve on intermediate-, long-term, and TAH increase in activity level and begin a regular **exercise** program. Eventually, with proper training about device maintenance, they are able to leave the hospital to live at home, returning to a normal lifestyle, until further medical treatment is required.

Mechanical debridement *see* **Debridement**

## Mechanical ventilation

### Definition

Mechanical ventilation is the use of a mechanical device (machine) to inflate and deflate the lungs.

### Purpose

Mechanical ventilation provides the force needed to deliver air to the lungs in a patient whose own ventilatory abilities are diminished or lost.

### Description

Breathing requires the movement of air into and out of the lungs. This is normally accomplished by the diaphragm and chest muscles. A variety of medical conditions can impair the ability of these muscles to accomplish this task, including:

- muscular dystrophies
- motor neuron disease, including ALS
- damage to the brain's respiratory centers
- polio
- myasthenia gravis
- myopathies affecting the respiratory muscles
- scoliosis

Mechanical ventilation may also be used when the airway is obstructed, especially at night in sleep apnea.

Mechanical ventilation may be required only at night, during limited daytime hours, or around the clock, depending on the patient's condition. Some patients require mechanical ventilation only for a short period, during recovery from traumatic nerve injury, for instance. Others require it chronically, and may increase the number of hours required over time as their disease progresses.

Mechanical ventilation is not synonymous with the use of an oxygen tank. Supplemental oxygen is used in patients whose gas exchange capacity has diminished, either through lung damage or obstruction of a major airway. For these patients, the muscles that deliver air work well, but too little oxygen can be exchanged in the remaining lung, and so a higher concentration is supplied with each breath. By the same token, many patients who require mechanical ventilation do not need supplemental oxygen. Their gas exchange capacity is normal, but they cannot adequately move air into and out of the lungs. In fact, excess oxygen may be dangerous, since it can suppress the normal increased respiration response to excess carbon dioxide in the lungs.

Mechanical ventilation systems come in a variety of forms. Almost all systems use a machine called a ventilator that pushes air through a tube for delivery to the patient's airways. The air may be delivered through a nasal or face mask, or through an opening in the trachea (windpipe), called a tracheostomy. Much rarer are systems that rhythmically change the pressure around a patient's chest when the pressure is low, air flows into the lungs, and when it increases, air flows out.

### *Ventilators*

Ventilators can either deliver a set volume with each cycle, or can be set to a specific pressure regimen. Both are in common use. Volume ventilator settings are adjustable for total volume delivered, timing of delivery, and whether the delivery is mandatory or determined by the patient's initial inspiratory effort.

Pressure ventilators deliver one of two major pressure regimens. Continuous positive airway pressure (CPAP) delivers a steady pressure of air, which assists the patient's inspiration (breathing in) and resists expiration (breathing out). The pressure of CPAP is not sufficient to completely inflate the lungs; instead its purpose is to maintain an open airway, and for this reason it is used in sleep apnea, in which a patient's airway closes frequently during sleep.

Bilevel positive airway pressure (BiPAP) delivers a higher pressure on inspiration, helping the patient obtain a full breath, and a low pressure on expiration, allowing the patient to exhale easily. BiPAP is a common choice for neuromuscular disease.

The choice of ventilator type is partly determined by the knowledge and preferences of the treating physician. Settings are adjusted to maintain patient comfort and appropriate levels of oxygen and carbon dioxide in the blood.

### *Masks vs. tracheostomy*

Delivery of air from a ventilator may be either through a mask firmly held to the face, or through a tube inserted into the trachea toward the bottom of the throat. A mask interface is called noninvasive ventilation, while a tracheostomy tube is called invasive ventilation.

Until the mid-1990s, invasive ventilation was the option used by virtually all patients requiring long-term mechanical ventilation. For some patients, tracheostomy continues to be a preferred option. It is commonly used when 24-hour ventilation assistance is required, and may be preferred by patients who find masks uncomfortable or unsightly. Some patients feel

ventilation through a "trach tube" is more reassuring. Tracheostomy is also the preferred option for most patients with swallowing difficulties. The potential to choke and suffocate on improperly swallowed food is avoided with a tracheostomy.

Tracheostomies may require more frequent suctioning of airway secretions, produced in response to the presence of the tube and the inflatable cuff that some patients require to hold it in place. The risk of infection is higher, and air must be carefully humidified and cleaned, since these functions are not being served by the nasal passages. Tracheostomies do not prevent speech, despite misinformation to the contrary that even some doctors believe. Speech requires passage of air around the trach tube, which can occur either with an uncuffed tube, or with the presence of a special valve that allows air passage past the cuff.

Noninvasive interfaces come in a variety of forms. A simple mouthpiece may be used, which a patient bites down on to seal the lips around the tube as the pressure cycle delivers a breath. Most masks are individually fitted to the patient's face, and held in place with straps. A tight fit is essential, since the pressure must be delivered to the patient's lungs, and not be allowed to blow out the sides of the mask. Masks may be used around the clock. Nasal masks do not prevent speech, though the tone may change. Oral or full-face masks do interfere with speech, and are typically used at night or intermittently throughout the day, for patients who do not need continuous ventilation assistance.

### *Other alternatives*

The iron lung was an early mechanical ventilation device, and is still in use in some hospitals. The patient's head remains outside of it, while the interior depressurizes. This allows air to push in to the lungs. Repressurizing deflates the lungs again.

A device that works on the same principle is the chest shell (something like a turtle's shell swung around to the front). The pneumobelt applies pressure to deflate, and relaxes it to allow inflation. A rocking bed is used for nighttime ventilation. Tilting the head of the bed down deflates the lungs by allowing the abdominal contents to press against the diaphragm. Reversing the angle reverses the process, allowing inflation.

### **Preparation**

Patients with diseases in which mechanical ventilation may be required are advised to learn as much as possible about treatment options before they become

necessary. In particular, it is important to learn about and make decisions about invasive vs. noninvasive ventilation before the time comes. Many patients who begin ventilation with emergency tracheostomy have a difficult time switching to noninvasive ventilation later on (though it is certainly possible).

It is often a good idea to try out different masks and other interfaces before their need arises, and to have these fitted in preparation for a planned transition to the ventilator. Patients can find support groups and other sources of information to learn more about the options and the features of each means of ventilation. Patients may have to help educate their doctors if they are not familiar with noninvasive options.

Patients with neuromuscular disease may have as much or more need for a deep cough as they do for ventilatory assistance, and many patients who undergo emergency tracheostomy do so because their airways have become clogged with mucus build up. Physical therapy cough assistance and a cough assist device are important options for full respiratory health.

### Normal results

Mechanical ventilation is a life saver, and provides comfort and confidence to patients who require it. Proper ventilation restores levels of oxygen and carbon dioxide in the blood, improving sleep at night and increasing the ability to engage in activities during the day. When combined with proper respiratory hygiene, it can prolong life considerably. Patients with progressive diseases such as ALS may wish to consider end-of-life decisions before commencing mechanical ventilation, or before the ability to communicate is lost.

## Meckel's diverticulectomy

### Definition

Meckel's diverticulectomy is a surgical procedure that isolates and removes an abnormal diverticulum (Meckel's diverticulum) or pouch, as well as surrounding tissue, in the lining of the small intestine. It is performed to remove an obstruction, adhesions, infection, or inflammation.

### Purpose

Meckel's diverticulum is an intestinal diverticulum (pouch) that results from the inability of the vitelline (umbilical) duct to close at five weeks of embryonic development. The vitelline duct is lined with layers of intestinal tissue containing cells that can develop into many different forms, called pluripotent cells. Meckel's diverticulum is a benign congenital condition that has no symptoms for some people, and develops complications in others.

Ninety percent of diverticula are close to the ileocecal valve in the upper intestine, and tissue made up predominantly of gastric and pancreatic cells is thought to cause chemical changes in the mucosa, or lining of the intestines.

The most common cells found in the mucosa of diverticula are gastric cells (present in 50% of all Meckel's diverticulum cases). The highly acidic secretions of gastric tissue may cause the early symptoms of Meckel's diverticulum. The alkaline secretions of pancreatic tissue are also thought to be a source of diverticula inflammation in a small number—about 5%—of cases.

Inflammation of the diverticula or infection of the intestines around the diverticula results in a condition known as **diverticulitis**, which may be treated with **antibiotics**. However, when it is acute and causes obstructions and bleeding, surgery is the treatment of choice.

### Demographics

Meckel's diverticulum is present in approximately 2% of the population. It is the most commonly encountered congenital anomaly of the small intestine. Although the abnormality occurs in both sexes, men have more

## KEY TERMS

**Diverticulitis**—Inflammation or infection of the diverticula of the intestines.

**Diverticulum**—Pouches or bulges of tissue in the lining of organs or canals that can become infected, especially in the intestines and esophagus.

**Littre's hernia**—A Meckel's diverticulum trapped in an inguinal hernia.

**Merkel's diverticulum**—Tissue faults in the lining of the intestines that are the result of a congenital abnormality originating in the umbilical duct's failure to close. Largely asymptomatic, the diverticula in some cases can become infected or obstructed.

**Perforation**—The rupture or penetration by injury or infection of the lining of an organ or canal that allows infection to spread into a body cavity, as in peritonitis, the infection of the lining of the stomach or intestines.

frequent complications with the condition and are more often diagnosed with it. One 15-year study set the complication risk of the abnormality at 4.2%. A recent 10-year study done retrospectively reported an even age distribution for complications of the diverticulum. Malignancy is found in only 0.5–4.9% of patients with complications of Meckel's diverticulum.

## Description

Open surgery of the intestines is indicated in acute cases. In the surgery, the intestinal segment containing the diverticulum, usually the ileum or upper intestines, is removed. After the diverticulum is removed, the healthy portions of the intestine are joined together. Some debate exists about whether surgery for asymptomatic Meckel's diverticulum found incidentally is recommended. Some researchers have shown that preventive removal of the diverticulum is less risky than surgical complications, and point to the fact that 6.4% of patients with Meckel's diverticulum develop complications of the condition over their lifetime.

Depending on the surgeon's decision, the operation may be minimal, isolating and then removing the pouch containing the inflammation, or it may be more extensive. In the latter cases, surrounding tissue is removed due to the presence of pervasive inflammation, obstruction, or incarceration in an inguinal hernia (Littre's hernia). Removing additional tissue is done to prevent recurrences. Recent studies have demonstrated the

feasibility of laparoscopic, or minimally invasive diverticulectomy, utilizing small incisions and video imagery via tiny cameras. No long-term studies of this procedure have been conducted.

Surgery is performed under general anesthetic. The small intestine is isolated and the diverticulum is removed, sometimes with a small segment of the intestines. Operative techniques are used to conjoin the end sections of the intestines that have been severed. Some surgeons prefer to perform two surgeries, and do not join together the intestinal sections until some healing of the segments has occurred. In this case, a stoma, or temporary outlet for tubal connection to the intestines, is created in the wall of the abdomen where an external appliance, called an ostomy, can receive waste until the intestinal sections are rejoined.

## Diagnosis/Preparation

The vast majority of Meckel's diverticulum diagnoses are incidental, that is, discovered during barium studies, abdominal surgery for other conditions, or autopsy. The most common symptom of the condition is intestinal bleeding, which occurs in 25–50% of patients who have complications. Hemorrhage is the most significant symptom in children two years old and younger. Intestinal obstructions are common, resulting from complications of the tissue surrounding the diverticula. Symptomatic Meckel's diverticulum has symptoms similar to appendicitis. Lower abdominal pain or diverticulitis accounts for 10–20% of cases, and requires careful diagnosis to distinguish it from appendicitis. Left untreated, diverticulitis can lead to perforation of the intestine and peritonitis.

Patients who have diverticulitis symptoms, such as acute abdominal pain are given various imaging tests, including a CT scan, **colonoscopy**, or a **sigmoidoscopy** (view of the lower colon through a tiny video instrument placed in the rectum). For children, a special chemical diagnostic test of sodium Tc-pertechnetate, a radioisotope that reacts to the mucosa in the diverticulum, allows inflammation or infection to be viewed radiographically. In adult patients, barium studies may help with diagnosis. When acute hemorrhaging is present, MR imaging of blood vessels is an effective diagnostic tool.

If surgery is indicated for Meckel's diverticulum, an enema is given (unless contraindicated by complications) to completely clear the bowel and avoid infection during surgery.

## Aftercare

Intestinal surgery is a serious procedure, and recovery may take two weeks. The number of

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

Surgery takes place in a hospital setting by a physician with advanced training in surgery and gastrointestinal surgery. If the surgery is minimally invasive, requiring only small incisions, it may be performed in an outpatient surgical area of the hospital.

postoperative days spent in the hospital depends on the extent of the diverticulum surgery and complications of the condition prior to surgery. Barring complications, patients usually stay in the hospital for about one week. Immediately after surgery, the patient is observed carefully, and given intravenous fluids and antibiotics. Surgical catheters, or stents, are removed over the next two days, with food by mouth offered once bowel sounds are heard.

### Risks

Intestinal surgery has the surgical complications associated with any open surgery. These include lung and heart complications, as well as reactions to medications, bleeding, and infection.

### Normal results

The usual results of this surgery are an end to obstruction, pain, and infection. Highly successful results include the return of bowel function and daily activities.

### Morbidity and mortality rates

Patients with complications of Meckel's diverticulum have a 10–12% incidence of early postoperative complications such as an intestinal leak, a suture line leak or intra-abdominal abscess. Later complications occur in about 7% of patients, and include bowel obstructions and intestinal adhesions. The reported mortality rate for surgery on patients with symptomatic diverticulum is 2–5%. With asymptomatic patients who undergo incidental diverticulectomy, both early and late complications occur in 2% of cases, and the mortality rate is 1%.

### Alternatives

Diverticulitis is routinely treated with a change in diet that includes increasing bulk with high-fiber foods

## QUESTIONS TO ASK THE DOCTOR

- Is this surgery necessary or can changing the diet and medical treatment be just as effective?
- Because this surgery was performed on an emergency basis, how extensive was the surgery and how much of the intestine was removed?

and bulk additives like Metamucil. Recurrent attacks, perforation, tissue adhesions, or infections are initially treated with antibiotics, a liquid diet, and bed rest. If medical treatment does not clear the complications, **emergency surgery** may be required.

## Mediastinoscopy

### Definition

Mediastinoscopy is a surgical procedure that allows physicians to view areas of the mediastinum, the cavity behind the sternum (breastbone) that lies between the lungs. The organs in the mediastinum

(Cengage Learning, Gale.)

include the heart and its vessels, the lymph nodes, trachea, esophagus, and thymus.

Mediastinoscopy is most commonly used to detect or stage cancer. It is also ordered to detect infection, and to confirm diagnosis of certain conditions and diseases of the respiratory organs. The procedure involves insertion of an endotracheal (within the trachea) tube, followed by a small incision in the chest. A mediastinoscope is inserted through the incision. The purpose of this equipment is to allow the physician to directly see the organs inside the mediastinum, and to collect tissue samples for laboratory study.

### Purpose

Mediastinoscopy is often the diagnostic method of choice for detecting lymphoma, including Hodgkin's disease. The diagnosis of sarcoidosis (a chronic lung disease) and the staging of lung cancer can also be accomplished through mediastinoscopy. Lung cancer staging involves a determination of the level or progression of the cancer into stages. These stages help a physician study cancer and provide consistent cancer definition levels and corresponding treatments. They also provide some guidance as to prognosis. The lymph nodes in the mediastinum are likely to reveal if lung cancer has spread beyond the lungs. Mediastinoscopy allows a physician to observe and extract a sample from the nodes for further study. Involvement of these lymph nodes indicates the diagnosis and stage of lung cancer.

Mediastinoscopy may also be ordered to verify a diagnosis that was not clearly confirmed by other methods, such as certain radiographic and laboratory studies. Mediastinoscopy may aid in some surgical biopsies of nodes or cancerous tissue in the mediastinum. In fact, a surgeon may immediately perform a surgical procedure if a malignant tumor is confirmed while the patient is undergoing mediastinoscopy. In these cases, the diagnostic exam and surgical procedure are combined into one operation.

Mediastinoscopy provides a diagnosis in 10–75% of cases, depending on histology, location, and size of cancer. The false positive rate, however can be as high as 20%.

### Demographics

Approximately 130,000 new pulmonary nodules are diagnosed each year in the United States. Of those, half are malignant. The majority of pulmonary nodules are diagnosed via mediastinoscopy.

## KEY TERMS

**Endotracheal**—Placed within the trachea, also known as the windpipe.

**Hodgkin's disease**—A malignancy of lymphoid tissue found in the lymph nodes, spleen, liver, and bone marrow.

**Lymph nodes**—Small round structures located throughout the body; contain cells that fight infections.

**Pleural space**—Space between the layers of the pleura (membrane lining the lungs and thorax).

**Sarcoidosis**—A chronic disease characterized by nodules in the lungs, skin, lymph nodes, and bones; however, any tissue or organ in the body may be affected.

**Thymus**—An unpaired organ in the mediastinal cavity that is important in the body's immune response.

### Description

Mediastinoscopy is usually performed in a hospital under **general anesthesia**. Before the general anesthesia is administered, **local anesthesia** is applied to the throat while an endotracheal tube is inserted. Once the patient is under general anesthesia, a small incision is made, usually just below the neck or at the notch at the top of the sternum. The surgeon may clear a path and feel the person's lymph nodes first to evaluate any abnormalities within the nodes. Next, the physician inserts the mediastinoscope through the incision. The scope is a narrow, hollow tube with an attached light that allows the surgeon to see inside the area. The surgeon can insert tools through the hollow tube to help perform biopsies. A tissue sample from the lymph nodes or a mass can be removed and sent for study under a microscope, or to a laboratory for further testing.

In some cases, tissue sample analysis that shows malignancy will suggest the need for immediate surgery while the person is already prepared and under anesthesia. In other cases, the surgeon will complete the visual study and tissue removal, and stitch the small incision closed. The person will remain in the surgical recovery area until the effects of anesthesia have lessened and it is safe to leave the area. The entire procedure should require about an hour, not counting preparation and recovery time. Studies have shown that mediastinoscopy is a safe, thorough, and cost-effective diagnostic tool with less risk than some other procedures.

## Diagnosis/Preparation

Because mediastinoscopy is a surgical procedure, it should only be performed when the benefits of the exam's findings outweigh the risks of surgery and anesthesia. Individuals who previously had mediastinoscopy should not receive it again if there is scarring from the first exam.

Several other medical conditions, such as impaired cerebral circulation, obstruction or distortion of the upper airway, or thoracic aortic aneurysm (abnormal dilation of the thoracic aorta) may also preclude mediastinoscopy. Certain structures in a person's anatomy that can be compressed by the mediastinoscope may complicate these pre-existing medical conditions.

Patients are asked to sign a consent form after reviewing the risks of mediastinoscopy and known risks and reactions to anesthesia. The physician will normally instruct the patient to fast from midnight before the test until after the procedure is completed. A physician may also prescribe a sedative the night before the exam and again before the procedure. Often a local anesthetic will be applied to the throat to prevent discomfort during placement of the endotracheal tube.

## Aftercare

Following mediastinoscopy, patients will be carefully monitored and watched for changes in **vital signs**, or symptoms of complications from the procedure or anesthesia. The patient may have a sore throat from the endotracheal tube, experience temporary chest pain, and have soreness or tenderness at the incision site.

## Risks

Complications from the actual mediastinoscopy procedure are relatively rare. The overall complication rates in various studies have been reported in the range of 1.3–3%. However, the following complications, in decreasing order of frequency, have been reported:

- hemorrhage
- pneumothorax (air in the pleural space)
- recurrent laryngeal nerve injury, causing hoarseness
- infection
- tumor implantation in the wound
- phrenic nerve injury (injury to a thoracic nerve)
- esophageal injury
- chylothorax (chyle is milky lymphatic fluid in the pleural space)
- air embolism (air bubble)
- transient hemiparesis (paralysis on one side of the body)

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

A mediastinoscopy procedure is usually performed by a thoracic or general surgeon in a hospital setting.

The usual risks associated with general anesthesia also apply to this procedure.

## Normal results

In the majority of procedures performed to diagnose cancer, a normal result indicates the presence of small, smooth lymph nodes with no abnormal tissue, growths, or signs of infection. In the case of lung cancer staging, results are related to the severity and progression of the cancer.

Abnormal findings may indicate lung cancer, tuberculosis, the spread of disease from one body part to another, sarcoidosis (a disease that causes nodules, usually affecting the lungs), lymphoma (abnormalities in the lymph tissues), and Hodgkin's disease.

## Morbidity and mortality rates

Complications of mediastinoscopy include bleeding, pain, and post-procedure infection. These are relatively uncommon. Mortality is extremely rare.

## Alternatives

A less invasive technique is **ultrasound**. However, it is not as specific as mediastinoscopy, and the information obtained is not as useful in making a diagnosis.

Although still performed, there is a decline in the use of mediastinoscopy as a result of advancements in computed tomography (CT), **magnetic resonance imaging** (MRI), and ultrasonography techniques. In addition, improved fine-needle aspiration (withdrawing fluid using suction) results of and core-needle biopsy (using a needle to obtain a small tissue sample) investigations, along with new techniques in thoracoscopy (examination of the thoracic cavity with a lighted instrument called a thoracoscope) offer additional options in examining masses in the mediastinum. Mediastinoscopy may be required when other methods cannot be used or when they provide inconclusive results.

## QUESTIONS TO ASK THE DOCTOR

- Why is this test needed?
- Is the test dangerous?
- What test preparation is required?
- How long will the test take?
- When will the results be available?
- What form of anesthesia will be used?
- Is the surgeon board certified?
- How many mediastinoscopy procedures has the surgeon performed?
- What is the surgeon's complication rate?

## Medicaid

### Definition

Medicaid is a federal-state entitlement program for low-income citizens of the United States. The Medicaid program is part of Title XIX of the Social Security Act Amendment that became law in 1965. Medicaid offers federal matching funds to states for costs incurred in paying health care providers for serving covered individuals. State participation is voluntary, but since 1982, all 50 states have chosen to participate in Medicaid.

### Description

#### Medicaid benefits

Medicaid benefits cover basic health care and long-term care services for eligible persons. About 58% of Medicaid spending covers hospital and other acute care services. The remaining 42% pays for nursing home and long-term care.

States that choose to participate in Medicaid must offer the following basic services:

## KEY TERMS

**Categorically needy**—A term that describes certain groups of Medicaid recipients who qualify for the basic mandatory package of Medicaid benefits. There are categorically needy groups that states participating in Medicaid are required to cover, and other groups that the states have the option to cover.

**Department of Health and Human Service (DHHS)**—It is a federal agency that houses the Centers for Medicare and Medicaid Services, and distributes funds for Medicaid.

**Entitlement**—A program that creates a legal obligation by the federal government to any person, business, or government entity that meets the legally defined criteria. Medicaid is an entitlement both for eligible individuals and for the states that decide to participate in it.

**Federal poverty level (FPL)**—The definition of poverty provided by the federal government, used as the

reference point to determine Medicaid eligibility for certain groups of beneficiaries. The FPL is adjusted every year to allow for inflation.

**Health Care Financing Administration (HCFA)**—A federal agency that provides guidelines for the Medicaid program.

**Medically needy**—A term that describes a group whose coverage is optional with the states because of high medical expenses. These persons meet category requirements of Medicaid (they are children or parents or elderly or disabled) but their income is too high to qualify them for coverage as categorically needy.

**Supplemental Security Income (SSI)**—A federal entitlement program that provides cash assistance to low-income blind, disabled, and elderly people. In most states, people receiving SSI benefits are eligible for Medicaid.

- hospital care, both inpatient and outpatient
- nursing home care
- physician services
- laboratory and diagnostic x-ray services
- immunizations and other screening, diagnostic, and treatment services for children
- family planning
- health center and rural health clinic services
- nurse midwife and nurse practitioner services
- physician assistant services

Participating states may offer the following optional services and receive federal matching funds for them:

- prescription medications
- institutional care for the mentally retarded
- home- or community-based care for the elderly, including case management
- personal care for the disabled
- dental and vision care for eligible adults

Because participating states are allowed to design their own benefits packages as long as they meet federal minimum requirements, Medicaid benefits vary considerably from state to state. About half of all Medicaid spending covers groups of people and services above the federal minimum.

### *Eligibility for Medicaid*

Medicaid covers three major groups of low-income Americans:

- All recipients. In 2006, Medicaid covered an estimated 46.5 million low-income persons in the United States.
- Parents and children. In 2005, Medicaid covered approximately 25.2 million low-income children, approximately one-fifth of all children in the United States. It provided coverage to an estimated 10.2 million low-income adults in families with children; most of these low-income adults were women.
- The elderly. In 2006, Medicaid covered an estimated 5.8 million adults over the age of 65. Medicaid is the largest single purchaser of long-term and nursing home care in the United States.
- The disabled. About 17% of Medicaid recipients are blind or disabled. Most of these persons are eligible for Medicaid because they receive assistance through the Supplemental Security Income (SSI) program.

All Medicaid recipients must have incomes and resources below specified eligibility levels. These levels vary from state to state depending on the local cost of living and other factors. For example, in 2006, the federal poverty level (FPL) was determined to be \$16,600 for a family of three on the mainland of the United States, but \$24,900 in Hawaii and \$29,050 in Alaska.

In most cases, persons must be citizens of the United States to be eligible for Medicaid, although legal immigrants may qualify in some circumstances depending on their date of entry. Illegal aliens are not eligible for Medicaid, except for emergency care.

Persons must fit into an eligibility category to receive Medicaid, even if their income is low. Childless couples and single childless adults who are not disabled or elderly are not eligible for Medicaid.

### *Medicaid costs*

Medicaid is by far the government's most expensive general welfare program. In 1966, Medicaid accounted for 1.4% of the federal budget, but by 2006, its share had risen to nearly 9.1%. Combined federal and state spending for Medicaid takes approximately 21 cents of every tax dollar. The federal government covers about 56% of costs associated with Medicaid. The states pay for the remaining 44%.

As of 2006, costs for Medicaid continued to rise at an average annual rate of approximately 8%. The states spent \$303 billion in FY 2006 to cover Medicaid costs. These costs are projected to continue to increase.

Although more than half (54%) of all Medicaid beneficiaries are children, most of the money (more than 70%) goes for services for the elderly and disabled. The single largest portion of Medicaid money pays for long-term care for the elderly. Only 18% of Medicaid funds are spent on services for children.

There are several factors involved in the steep rise of Medicaid costs:

- The rise in the number of eligible individuals. As the lifespan of most Americans continues to increase, the number of elderly individuals eligible for Medicaid also rises. The fastest-growing age group in the United States is people over 85.
- The price of medical and long-term care. Advances in medical technology, including expensive diagnostic imaging tests, cause these costs to rise.
- The increased use of services covered by Medicaid.
- The expansion of state coverage from the minimum benefits package to include optional groups and optional services.

### **Normal results**

The need to contain Medicaid costs is considered one of the most problematic policy issues facing legislators. In addition, the complexity of the Medicaid system, its vulnerability to billing fraud and other abuses, the confusing variety of the benefits packages

available in different states, and the time-consuming paperwork are other problems that disturb both taxpayers and legislators.

Medicaid has increased the demand for health care services in the United States without greatly impacting or improving the quality of health care for low-income Americans. Medicaid is the largest health insurer in the United States. As such, it affects the employment of several hundred thousand health care workers, including health care providers, administrators, and support staff. Participation in Medicaid is optional for physicians and **nursing homes**. Many do not participate in the program because the reimbursement rates are low. As a result, many low-income people who are dependent on Medicaid must go to overcrowded facilities where they often receive substandard health care.

## Medical charts

### Definition

A medical chart is a confidential document that contains detailed and comprehensive information on an individual and the care experience related to that person. It is commonly called a medical record.

### Purpose

The purpose of a medical chart is to serve as both a medical and legal record of an individual's clinical status, care, history, and caregiver involvement. The specific information contained in the chart is intended to provide a record of a person's clinical condition by detailing diagnoses, treatments, tests and responses to treatment, as well as any other factors that may affect the person's health or clinical state.

### Demographics

Every person who has a professional relationship with a health-care provider has a medical record. Because most people have such relationships with

more than one health professional or caregiver, most people actually have more than one medical chart.

### Description

The terms medical chart or medical record are a general description of a collection of information on a person. However, different clinical settings and systems utilize different forms of documentation to achieve this purpose. As technology progresses, more institutions are adopting computerized systems that aid in clearer documentation, enhanced access and searching, and more efficient storage and retrieval of individual records.

New uses of technology have also raised concerns about confidentiality. Confidentiality, or personal privacy, is an important principle related to the chart. Whatever system may be in place, it is essential that the health-care provider protect an individual's privacy by limiting access only to authorized individuals. Generally, physicians and nurses write most frequently in the chart. Documentation by the clinician who is leading treatment decisions (usually a physician) often focuses on diagnosis and prognosis, while the documentation by members of the nursing team generally focuses on individual responses to treatment and details of day-to-day progress. In many institutions, the medical and nursing staff may complete separate forms or areas of the chart specific to their disciplines.

Other health-care professionals that have access to the chart include physician assistants; social workers; psychologists; nutritionists; physical, occupational, speech, or respiratory therapists; and consultants. It is important that the various disciplines view the notes written by other specialties in order to form a complete picture of a person and provide continuity of care. Quality assurance and regulatory organizations, legal bodies, and insurance companies may also have access to the chart for specific purposes such as documentation, institutional audits, legal proceedings, or verification of information for care reimbursement. It is important to know about institutional policies regarding chart access in order to ensure the privacy of personal records.

The medical record should be stored in a pre-designated, secure area and discussed only in appropriate and private clinical areas. All individuals have a right to view and obtain copies of their own records. Special state statutes may cover especially sensitive information such as psychiatric, communicable disease

## KEY TERMS

**Consultation**—Evaluation by an outside expert or specialist, someone other than the primary care provider.

**Continuity**—Consistency or coordination of details.

**Discipline**—In health care, a specific area of preparation or training such as social work, nursing, or nutrition.

**Documentation**—The process of recording information in the medical chart, or the materials contained in a medical chart.

**Interdisciplinary**—Consisting of several interacting disciplines that work together to care for an individual.

**Objective**—Not biased by personal opinion; repeatable.

**Prognosis**—Expected resolution or outcome of an illness or injury.

**Regulatory organization**—Organization designed to maintain or control quality in health care.

**Subjective**—Influenced by personal opinion, bias, or experience; not reliably repeatable.

(i.e., HIV), or substance abuse records. Institutional and government policies govern what is contained in the chart, how it is documented, who has access, and policies for regulating access to the chart and protecting its integrity and confidentiality. In those cases in which individuals outside of the immediate care system must access chart contents, an individual or personal representative is asked to provide permission before records can be released. Individuals are often asked to sign these releases so that caregivers in new clinical settings may review their charts.

## Diagnosis/Preparation

### Training

Thorough training is essential prior to independent use of the medical chart. Whenever possible, a new clinician should spend time reviewing the chart to get a sense of organization and documentation format and style. Training programs for health-care professionals often include practice in writing notes or flow charts in mock medical records. Notes by trainees are often initially cosigned by supervisors to ensure accurate and relevant documentation and document-appropriate supervision.

### Operation

Documentation in the medical record begins when an individual enters the care system, which may be a specific place such as a hospital or professional office, or a program such as a home health-care service. Frequently, a facility will request permission to obtain copies of previous records so that they have complete information on the person. Although chart systems vary from institution to institution, there are many aspects of the chart that are universal. Frequently used chart sections include the following:

- Admission paperwork. Includes legal paperwork such as a living will or health care proxy, consents for admission to the facility or program, demographics, and contact information.
- History and physical. Contains comprehensive review of an individual's medical history and physical examinations.
- Orders. Contains medication and treatment orders by the doctor, nurse practitioner, physician assistant, or other qualified health-care team members.
- Medication record. Documents all medications administered.
- Treatment record. Documents all treatments received such as dressing changes or respiratory therapy.
- Procedures. Summarizes diagnostic or therapeutic procedures, i.e., colonoscopy or open-heart surgery.
- Tests. Provides reports and results of diagnostic evaluations, such as laboratory tests and electrocardiography tracings or radiography images or summaries of test results.
- Progress notes. Includes regular notes on the individual's status by members of the interdisciplinary care team.
- Consultations. Contains notes from specialized diagnosticians or external care providers.
- Consents. Includes permissions signed by the individual for procedures, tests, or access to chart. May also contain releases such as the release signed by any person when leaving the facility against medical advice (AMA).
- Flow records. Tracks specific aspects of professional care that occur on a routine basis, using tables or in a chart format.
- Care plans. Documents treatment goals and plans for future care within a facility or following discharge.
- Discharge. Contains final instructions for the person and reports by the care team before the chart is closed and stored following discharge.
- Insurance information. Lists health care benefit coverage and insurance provider contact information.

These general categories may be further divided by individual facilities for their own purposes. For example, a psychiatric facility may use a special section for psychometric testing, or a hospital may provide sections specifically for operations, x-ray reports, or electrocardiograms. In addition, certain details such as allergies or do not resuscitate orders may be displayed prominently (for instance, with large colored stickers or special chart sections) on the chart in order to communicate uniquely important information. It is important for health-care providers to become familiar with the charting systems in place at their specific facilities or programs.

It is important that the information in the chart be clear and concise, so that those utilizing the record can easily access accurate information. The medical chart can also aid in clinical problem solving by tracking an individual's baseline, or status on admission or entry into an office or health care system; orders and treatments provided in response to specific problems; and individual responses. Another reason for the standard of clear documentation is the possibility that the record may be used in legal proceedings, when documentation serves as evidence in exploring and evaluating a person's care experience. When medical care is being referred to or questioned by the legal system, chart contents are frequently cited in court. For all of these purposes, certain practices that protect the integrity of the chart and provide essential information are recommended for adding information and maintaining the chart. These practices include the following:

- Date and time should be included on all entries.
- A person's full name and other identifiers (i.e., medical record number, date of birth) on all records.
- Continued records should be marked clearly (i.e., if a note is continued on the reverse side of a page).
- Each page of documentation should be signed.
- Blue or black non-erasable ink should be used on handwritten records.
- Records should be maintained in chronological order.
- Disposal or obliteration of any records or portions of records should be prevented.
- Documentation errors and corrections should be noted clearly, i.e., by drawing one line through the error and noting the presence of an error, and then initialing the area.
- Excess empty space should be avoided on the page. A line should be drawn through any unused space, the initial, time, and date included.
- Only universally accepted abbreviations should be used.

- Unclear documentation such as illegible penmanship should be avoided.
- Contradictory information should be avoided. For example, if a nurse documents that a person has complained of abdominal pain throughout a shift, while a physician documents that the person is free of pain, these discrepancies should be discussed and clarified. The resolution should be entered into the chart and signed by all parties involved in the disagreement.
- Objective rather than subjective information should be included. For example, personality conflicts between staff should not enter into the notes. All events involving an individual should be described as objectively as possible, i.e., describe a hostile person by simply stating the facts such as what the person said or did and surrounding circumstances or response of staff, without using derogatory or judgmental language.
- Any occurrence that might affect the person should be documented. Documented information is considered credible in court. Undocumented information is considered questionable since there is no written record of its occurrence.
- Current date and time should be used in documentation. For example, a note is added after the fact, it should be labeled as an addendum and inserted in correct chronological order, rather than trying to insert the information on the date of the actual occurrence.
- Actual statements of people should be recorded in quotes.
- The chart should never be left in an unprotected environment where unauthorized individuals may read or alter the contents.

Several methods of documentation have arisen in response to the need to accurately summarize a person's experience. In the critical care setting, flow records are often used to track frequent personal evaluations, checks of equipment, and changes of equipment settings that are required. Flow records also offer the advantages of displaying a large amount of information in a relatively small space and allowing for quick comparisons. Flow records can also save time for a busy clinician by allowing for the completion of checklists versus requiring written narrative notes.

Narrative progress notes, while more time consuming, are often the best way to capture specific information about an individual. Some institutions require only charting by exception (CBE), which requires notes only for significant or unusual findings. While this method may decrease repetition and lower

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

All members of a health-care team or individuals who render professional health-care services usually make entries into medical records. Health-care records are maintained in hospitals or other clinical settings and professional offices. Insurance companies and corporations may maintain limited health-care records or obtain copies of records created by other health-care providers.

required documentation time, most institutions that use CBE notes also require a separate flow record that documents regular contact with a person. Many facilities or programs require notes at regular intervals even when there is no significant occurrence, i.e., every nursing shift. Frequently used formats in individual notes include SOAP (subjective, objective, assessment, plan) notes. SOAP notes use an individual's subjective statement to capture an important aspect of care, follow with a key objective statement regarding the person's status, a description of the clinical assessment, and a plan for how to address individual problems or concerns. Focus charting and PIE (problem-intervention-evaluation) charting use similar systems of notes that begin with a particular focus such as a nursing diagnosis or an individual concern. Nursing diagnoses are often used as guides to nursing care by focusing on individual care-recipient needs and responses to treatment. An example of a nursing diagnosis is fluid volume for someone who is dehydrated. The notes would then focus on assessment for dehydration, interventions to address the problem, and a plan for continued care such as measurement of input and output and intravenous therapy.

### Aftercare

Current medical charts are maintained by members of the health-care team and usually require clerical assistance such as a unit clerk in the hospital setting or records clerk in a professional office. No alterations should be made to the record unless they are required to clarify or correct information and are clearly marked as such. After discharge, the medical records department of a facility checks for completeness and retains the record. Similar checks may be made in professional office settings. Sometimes, the record will be made available in another format, i.e., recording paper charts on microfilm or computer

## QUESTIONS TO ASK THE DOCTOR

- In a particular setting, who has the authority to make entries in a medical chart?
- Who has access to the chart?
- How is security maintained for medical records?

imaging. Institutional policies and state laws govern storage of charts on- and off-site and length of storage time required.

### Risks

A major potential risk associated with medical charts is breach of confidentiality. This must be safeguarded at all times. Other risks include loss of materials in a chart or incorrectly filing a chart so that subsequent retrieval is impeded or impossible.

### Normal results

All members of a health-care team require thorough understanding of the medical chart and documentation guidelines in order to provide competent care and maintain a clear, concise, and pertinent record. Health care systems often employ methods to guarantee thorough and continuous use and review of charts across disciplines. For example, nursing staff may be required to sign below every new physician order to indicate that this information has been communicated, or internal quality assurance teams may study groups of charts to determine trends in missing or unclear documentation. In legal settings, health-care team members may be called upon to interpret or explain chart notations as they relate to a specific legal case.

### Morbidity and mortality rates

Medical charts are made of paper or other materials. They are subject to deterioration or loss. Transporting them may cause lifting injuries, but not lead to disease or **death**.

### Alternatives

There are no alternatives for medical charts. Alternative mediums exist for paper records. These include fixing images on plastic media (photographs or x rays) or electronic storage. The latter can include magnetic tape or computer disks.

## Medical co-morbidities

### Definition

Morbidity is the presence of a disease state or disorder within a patient. Co-morbidity is the presence of more than one individual disease or disorder within the same patient. It is a state of having multiple distinct medical conditions at the same time.

(Medical-on-Line / Alamy)

## Demographic

Co-morbidities may be present in anyone regardless of age, but certain populations are more prone to having co-morbidities. Patients that are an advanced age are more vulnerable to medical problems than a younger patient demographic. Certain medical conditions are also prone to association with co-morbidities. For example, diabetes, psychiatric diseases, and cancer (especially in the elderly) are very frequently associated with co-morbid health conditions.

## Description

Co-existing or co-morbid conditions are sometimes commonly associated with a particular disease. For example, cancer patients may frequently have co-existing major depression. Diabetes patients may frequently have co-morbidities involving the cardiovascular system, kidney, and the eye. Chronic diseases are often co-morbid with depression.

Having co-morbidities also increases the risks associated with some surgical procedures. Co-morbidities may complicate the diagnosis of a new disease, especially if there are overlapping symptoms between the two. Co-morbidities have an impact on the type of treatment chosen for a patient, as well as the patient's prognosis. A patient's disease burden may have a health impact that is greater than the sum of the impact of the individual diseases. The medical outcome of co-morbid conditions may be very severe.

## The Charlson Co-morbidity Index

There are many systems that endeavor to standardize the "weight" of the medical impact of different co-morbidities. The end result is to predict the medical outcome or mortality that may result from the presence of specific co-morbidities. There are no systems that have currently been developed that accurately and completely assess this issue and are considered a true medical standard. However, one commonly used system is the Charlson Index, which has been validated and is the most widely accepted of the assessments.

The Charlson Co-morbidity Index attempts to predict the one-year mortality for patients with more than one medical disease or disorder. Each medical condition is categorized according to a set of codes known as the International Statistical Classification of Diseases and Related Health Problems, or ICD Codes. Each ICD Code represents a medical condition and is assigned a specific number that represents the medical weight of the disease. The score assigned to each disease is based on the risk of fatality within one

year associated with the disease. Additional points may be added for age, with each decade over forty being one point. The sum of the scores for each co-morbidity gives a total score that represents the risk of **dying**. The higher the score, the greater the risk of dying. This score assists physicians in determining how to treat patients with multiple co-morbidities. For example, if one patient has cancer, but also very severe co-morbidities, it may not be appropriate to subject the patient to difficult treatments because of the reduced likelihood of survival associated with the co-morbidity.

## Co-morbidity of Psychiatry

In psychiatry, a co-morbidity is defined as a diagnosis that exists simultaneously with another diagnosis. However, psychiatric co-morbidities may not represent the presence of multiple disorders. Rather they represent the number of diagnoses necessary to accurately describe the full range of the patient's symptoms. The severity of a patient's mental illness has a strong association with the number of co-morbid disorders present. Treatment of psychiatric diseases and disorders are impacted by co-morbidity, as the co-morbidity may render the normal treatment of an illness inappropriate. For example, some pharmaceutical treatments may cause symptoms of anxiety as a side effect. In a patient with an anxiety disorder as a co-morbidity, using this treatment for their primary illness would be inappropriate. Pharmaceutical treatments that have addictive potential are not appropriate for treatment of a primary illness in a patient with drug abuse as a co-morbidity. Drug abuse is often co-morbid with psychiatric disorders, and may be a consequence of the initial illness. Studies have shown that proper treatment of some psychiatric disorders may prevent the development of drug abuse problems.

Providing treatment for patients with co-morbidities that address and do not aggravate all the aspects of their various disorders can be challenging for health care providers. Co-morbidities in psychiatry can be controversial to diagnose as distinct disorders. For example, does a patient with drug abuse problems as well as bulimia (binging on food and then purging through vomiting) have two separate illnesses, or do they have a single disorder involving impulse control? Whether some co-morbidities are truly separate diagnoses or all part of one disorder can be difficult to judge.

## Co-morbidity of Diabetes

Diabetes is associated with many different co-morbidities. The increased blood glucose that is part

## QUESTIONS TO ASK YOUR DOCTOR

- Do I have co-morbid health conditions?
- Are my co-morbidities truly distinct from each other, or could they be related?
- What can I do to address health concerns regarding my co-morbid conditions?
- Do any of my treatments for primary illness have an adverse impact on one of my co-morbid health conditions?
- Do any of my co-morbidities have an adverse impact on treatment for my primary illness?

of the disease process can be very damaging to the blood vessels and the organ systems. Some of the co-morbidities associated with diabetes were previously believed to be separate from the course of the diabetes disease. It is controversial whether the co-morbidities associated with diabetes are distinct diseases or are a result of the diabetes itself, which is increasingly referred to as “metabolic syndrome”. Regardless of their source, the co-morbidities associated with diabetes have a significant impact on the overall health profile of the patient.

Patients with diabetes often develop vascular complications, which are medical problems of the blood vessels. Damaged blood vessels are a serious complication, as they affect all the organ systems. Excess blood glucose can also directly damage organs. In diabetics, there are often medical complications seen with the kidneys, the retina of the eye, the peripheral nervous system, heart disease, and stroke or peripheral artery disease. Tight control of blood glucose levels may help to prevent the development of complications and these co-morbidities of diabetes.

### Co-morbidity of Cancer in Elderly Patients

Patients above 65 years of age statistically bear a large proportion of cancer cases seen in the United States. In addition to cancer, the elderly are vulnerable to many different health conditions such as pulmonary disease, heart disease, and hypertension. Having co-morbidities with cancer has a great impact on decisions made by the patient and the physician regarding treatment choices. When an elderly person is newly diagnosed with cancer and has other existing medical conditions, each health problem needs to be evaluated in the context of its predicted impact on the course of the cancer. Awareness and evaluation of co-

## KEY TERMS

**Bulimia**—Psychiatric disorder involving eating large amounts of food in a short time period and then vomiting to purge the contents of the stomach.

**Cardiovascular System**—The physiological system including the heart and the blood vessels.

**Metabolic Syndrome**—A combination of medical disorders including diabetes, high blood pressure, and heart disease.

**Pulmonary Disease**—Disease involving the lungs.

morbidities is crucial to optimize care of a cancer patient, and may alter the appropriateness of treatment options. Quality of life, limiting the potential complications seen with treatment, and preventing recurrence of cancer are all impacted by how the co-morbidities are managed.

The existence of co-morbidities with cancer also affects the patient’s prognosis for survival. Because of this, physicians must often make treatment choices in the context of the likelihood of survival. For example a physician and patient may need to decide whether it is worth putting the patient through the rigors of chemotherapy, when congestive heart failure may already be severely limiting the patient’s life span in the short term. In some cases, the cancer treatment may cause mortality because of the co-morbidities. The co-morbidity may increase and amplify the adverse effects normally seen with some types of cancer treatment. This may limit the amount of medical assistance available to a cancer patient. Depending on their nature and severity, co-morbidities in cancer may create a far more severe overall health profile and prognosis for a patient.

## Medical errors

### Introduction and definitions

The subject of medical errors is not a new one. However, it did not come to widespread attention in the United States until the 1990s, when government-sponsored research about the problem was undertaken by two physicians, Lucian Leape and David Bates. In 1999, a report compiled by the Committee on Quality of Health Care in America and published by the Institute of Medicine (IOM) made headlines with its findings. As a result of the IOM report, President Clinton asked the Quality Interagency Coordination Task Force (QuIC) to analyze the problem of medical errors and patient safety, and make recommendations for improvement. The Report to the President on Medical Errors was published in February 2000.

It is important to understand the terms used by the government and health care professionals in describing medical errors in order to distinguish between injury or **death** resulting from mistakes made by people on the one hand, and unfortunate results of treatment on the other. Some allergic reactions to medications or failures to respond to cancer treatment, for example, result from physical differences among patients or the known side effects of certain treatments, and not from prescribing the wrong drug or therapy for the patient's condition. This type of negative outcome is called an adverse event in official documents. Adverse events can be defined as undesirable and unintentional, though not necessarily unexpected, results of medical treatment. An example of an adverse event is discomfort in an artificial joint that continues after the expected recovery period, or a chronic headache following a spinal tap.

A medical error, on the other hand, is an adverse event that could be prevented given the current state of medical knowledge. The QuIC task force expanded the IOM's working definition of a medical error to cover as many types of mistakes as possible. Their definition of a medical error is as follows: "The failure of a planned action to be completed as intended or the use of a wrong plan to achieve an aim. Errors can include problems in practice, products, procedures, and systems." The National Patient Safety Foundation (NPSF) prefers the term "healthcare error" to "medical error," and defines such errors as follows: "An unintended healthcare outcome caused by a defect in the delivery of care to a patient. Healthcare errors may be errors of commission (doing the wrong thing), omission (not doing the right thing), or execution (doing the right thing incorrectly)." A useful brief definition of a medical error is that it is a preventable adverse event.

### Statistics

The statistics contained in the IOM report were startling. The authors of the report stated that between 45,000 and 98,000 Americans die each year as the result of medical errors. If the lower figure is used as an estimate, deaths in hospitals resulting from medical errors are the eighth leading cause of mortality in the United States, surpassing deaths attributable to motor vehicle accidents (43,458), breast cancer (42,297), and AIDS (16,516). Moreover, these figures refer only to hospitalized patients; they do not include people treated in outpatient clinics, **ambulatory surgery centers**, doctors' or dentists' offices, college or military health services, or **nursing homes**. Medical errors certainly occur outside hospitals; in 1999, the Massachusetts State Board of Registration in Pharmacy estimated that 2.4 million prescriptions are filled incorrectly each year in that state—which is only one of 50 states.

In terms of health-care costs, the IOM report estimated that medical errors cost the United States about \$37.6 billion each year; about half this sum pays for direct health care.

Medical errors also carry a high psychological cost; according to a poll conducted by the National Patient Safety Foundation, 42% of the respondents had been affected personally by a medical error or had a friend or family member affected by one. The respondents rated the American health care system overall as only moderately safe, giving it a score of 4.9 on a 1–7 point scale, in which 7 was defined as very safe and 1 as very unsafe.

## KEY TERMS

**Adverse event**—An undesirable and unintended result of a medical treatment or intervention.

**Medical error**—A preventable adverse event.

**Systems analysis**—An approach to medical errors and other management issues that looks for problems in the work process rather than singling out individuals as bad or incompetent.

The United States is not unique in having a high rate of medical errors. The United Kingdom, Australia, and Sweden are presently undertaking studies of their respective health-care systems. British experts estimate that 40,000 patients die each year in the United Kingdom as the result of medical errors. Australia has been testing a new system for reporting errors since 1995.

### Description

There is no single universally accepted method of classifying medical errors in order to describe them more fully. The 2000 QuIC report lists five different classification schemes that have been used:

- type of health care given (medication, surgery, diagnostic imaging, etc.)
- severity of the injury (minor discomfort, serious injury, death, etc.)
- legal definitions (negligence, malpractice, etc.)
- setting (hospital, emergency room, intensive care unit, nursing home, etc.)
- persons involved (physician, nurse, pharmacist, patient, etc.)

The importance of these different ways to classify medical errors is their indication that different types of errors require different approaches to prevention and problem solving. For example, medication errors are often related to such communication problems as misspelled words or illegible handwriting, whereas surgical errors are often related to unclear or misinterpreted diagnostic images.

### Causes of medical errors

The causes of medical errors are complex and not yet completely understood. Some causes that have been identified include the following:

- Communication errors. One widely publicized case from 1994 involved the death of a Boston newspaper columnist from an overdose of chemotherapy for

breast cancer due to misinterpretation of the doctor's prescription; the patient was given four times the correct daily dose, when the doctor intended the dosage to be administered instead over a four-day period. Other cases involve medication mix-ups due to drugs with very similar names. The Food and Drug Administration (FDA) has identified no fewer than 600 pairs of look-alike or sound-alike drug names since 1992.

- The increasing specialization and fragmentation of health care. The more people involved in a patient's treatment, the greater the possibility that important information will be missing along the chain.
- Human errors resulting from overwork and burn-out. For some years, hospital interns, residents, and nurses have attributed many of the errors made in patient care to the long hours they are expected to work, many times with inadequate sleep. With the coming of managed care, many hospitals have cut the size of their nursing staff and require those that remain to work mandatory overtime shifts. A study published in the *Journal of the American Medical Association* in October 2002 found a clear correlation between higher-than-average rates of patient mortality and higher-than-average ratios of patients to nurses.
- Manufacturing errors. Instances have been reported of blood products being mislabeled during the production process, resulting in patients being given transfusions of an incompatible blood type.
- Equipment failure. A typical example of equipment failure might be intravenous pump with a malfunctioning valve, which would allow too much of the patient's medication to be delivered over too short a time period.
- Diagnostic errors. A misdiagnosed illness can lead the doctor to prescribe an inappropriate type of treatment. Errors in interpreting diagnostic imaging have resulted in surgeons operating on the wrong side of the patient's body. Another common form of diagnostic error is failure to act on abnormal test results. As of 2006, studies of autopsies in the United States indicated that doctors misdiagnosed fatal illnesses about 20% of the time.
- Poorly designed buildings and facilities. Hallways that end in sharp right angles, for example, increase the likelihood of falls or collisions between people on foot and patients being wheeled to an operating room.

### Ways of thinking about medical errors

One subject that has been emphasized in recent reports on medical errors is the need to move away

from a search for individual culprits to blame for medical errors. This judgmental approach has sometimes been called the “name, shame, and blame game.” It is characterized by the belief that medical errors result from inadequate training or from a few “bad apples” in the system. It is then assumed that medical errors can be reduced or eliminated by identifying the individuals at fault, and firing or disciplining them. The major drawback of this judgmental attitude is that it makes health-care workers hesitate to report errors for fear of losing their own jobs or fear of some other form of reprisal. As a result of underreporting, hospital managers and others concerned with patient safety often do not have an accurate picture of the frequency of occurrence of some types of medical errors.

Both the IOM report and the QuIC report urge the adoption of a model borrowed from industry that incorporates systems analysis. This model emphasizes making an entire system safer rather than punishing individuals; it assumes that most errors result from problems with procedures and work processes rather than bad or incompetent people; and it analyzes all parts of the system in order to improve them. The industrial model is sometimes referred to as the continuous quality improvement model (CQI). Hospitals that are implementing error-reduction programs based on the CQI model have found that a non-punitive procedure for reporting medical errors has improved morale among the staff as well as significantly reduced the number of medical errors. At Columbia-Presbyterian Hospital, for example, patients as well as staff can report medical errors via the Internet, a telephone hotline, or paper forms.

### Proposals for improvement

Current proposals for reducing the rate of medical errors in the American health-care system include the following:

- Adopt stricter standards of acceptable error rates. One reason that industrial manufacturers have made great strides in product safety and error reduction is their commitment to improving the quality of the work process itself.
- Standardize medical equipment and build in mechanical safeguards against human error. Anesthesiology is the outstanding example of a medical specialty that has cut its error rate dramatically by asking medical equipment manufacturers to design ventilators with standardized controls and valves to prevent the oxygen content from falling below that of room air. These changes were the result of studies that showed that many medical errors resulted from doctors having to

use unfamiliar ventilators and accidentally turning off the oxygen flow to the patient.

- Improve the working conditions for nurses and other hospital staff. Recommendations in this area include redesigning hospital facilities to improve efficiency and minimize falls and other accidents, as well as reducing the length of nursing shifts below 12.5 hours. Since 2003, residency programs for physicians have been redesigned to lower the risk of medical errors caused by human fatigue. These changes resulted from rules imposed in July 2003 by the Accreditation Council for Graduate Medical Education (ACGME). The rules limit residents to an 80-hour work week and 24 continuous hours on call, and guarantee one day off each week.
- Make use of new technology to improve accuracy in medication dosages and recording patients' vital signs. Innovations in this field include giving nurses and residents handheld computers for recording patient data so that they do not have to rely on human memory for so many details. Another innovation that helped Veterans Administration (VA) hospitals cut the rate of medication errors was the introduction of a handheld wireless bar-coding system. After the system went into operation at the end of 1998, the number of medication errors in VA hospitals dropped by 70%.
- Develop a nationwide database for error reporting and analysis. At present, there is no unified system for tracking different types of medical errors. An error in liver transplantation in August 2002 that cost the life of a baby led several researchers to recognize that there is still no national registry recording transplant mismatches. As a result, no one knows how many cases occur each year, let alone find ways to improve the present system.
- Encourage patients to become more active participants in their own health care. This recommendation includes asking more questions and requesting adequate explanations from health-care professionals, as well as reporting medical errors.
- Address the fact that both patients and physicians have emotional as well as knowledge-related needs around the issue of medical errors. A report published in the *Journal of the American Medical Association* in February 2003 stated that patients clearly want emotional support from their doctors following an error, including an apology. The researchers also found, however, that doctors are as upset when an error occurs and, additionally, are unsure where to turn for emotional support.
- Adopt a teamwork rather than an individualistic approach to medical care. According to an article

published in 2005 in the *Annals of Internal Medicine*, health care teams make fewer mistakes than individuals.

### What patients can do

Patients are an important resource in lowering the rate of medical errors. The QuIC task force has put together some fact sheets to help patients improve the safety of their health care. One of these fact sheets, entitled “Five Steps to Safer Health Care,” gives the following tips:

- Do not hesitate to ask questions of your health-care provider, and ask him or her for explanations that you can understand.
- Keep lists of all medications, including over-the-counter items as well as prescribed drugs.
- Ask for the results of all tests and procedures, and find out what the results mean for you.
- Find out what choices are available to you if your doctor recommends hospital care.
- If your doctor suggests surgery, ask for information about the procedure itself, the reasons for it, and exactly what will happen during the operation.

This fact sheet, as well as a longer and more detailed patient fact sheet on medical errors, is available for free download from the Agency for Health Research and Quality (AHRQ) Website, or by telephone order from the AHRQ Publications Clearinghouse at (800) 358-9295. In addition, the AHRQ has set up a patient safety network website at <<http://www.psnet.ahrq.gov/index.aspx>>. The website has an extensive list of resources ranging from online articles and fact sheets to links to audiovisual materials, journal articles, government reports, and other online materials. The site is produced and maintained by a team of editors at the University of California, San Francisco.

## Medicare

### Definition

Medicare is a national health insurance program created and administered by the federal government in the United States to address the medical needs of older American citizens. Medicare is available to U.S. citizens 65 years of age and older and some people with disabilities under age 65.

### Description

Medicare is the largest health insurance program in the United States. The program was created as part of the Social Security Act Amendment in 1965 and was put into effect in 1966. At the end of 1966, Medicare served approximately 3.9 million individuals. As of 2003, it serves about 41 million people. There are 5.6 million Medicare beneficiaries enrolled in managed care programs.

In 1973, the Medicare program was expanded to include people who have permanent kidney failure and need dialysis or transplants and people under the age of 65 who have specific types of disabilities. Medicare was originally administered by the Social Security Administration, but in 1977, the program was transferred to

## KEY TERMS

**DHHS**—The Department of Health and Human Service. This federal agency houses the Centers for Medicare and Medicaid Services and distributes funds for Medicaid.

**Entitlement**—A program that creates a legal obligation by the federal government to any person, business, or government entity that meets the legally defined criteria. Medicare is an entitlement for eligible individuals.

**HCFA**—Health Care Financing Administration. A federal agency that provides guidelines for the Medicaid program.

**Medicare Part A**—Hospital insurance provided by Medicare, provided free to persons aged 65 and older.

**Medicare Part B**—Medical insurance provided by Medicare that requires recipients to pay a monthly premium. Part B pays for some medical services Part A does not.

the Health Care Financing Administration (HCFA), which is part of the United States Department of Health and Human Services (DHHS). The Centers for Medicare and **Medicaid** Services, an agency of the DHHS, is the administrative agency. This agency also administers Medicaid programs.

Medicare is an entitlement program similar to Social Security and is not based on financial need. Medicare benefits are available to all American citizens over the age of 65 because they or their spouses have paid Social Security taxes through their working years. Since Medicare is a federal program, the rules for eligibility remain constant throughout the nation and coverage remains constant regardless of where an individual receives treatment in the United States.

Medicare benefits are divided into two different categories referred to as Part A and Part B. Medicare Part A is hospital insurance that provides basic coverage for hospital stays and post-hospital nursing facilities, home health care, and **hospice** care for terminally ill patients. Most people automatically receive Part A when they turn 65 and do not have to pay a premium because they or their spouse paid Medicare taxes while they were working.

Medicare Part B is medical insurance. It covers most fees associated with basic doctor visits and laboratory testing. It also pays for some outpatient medical

services such as medical equipment, supplies, and home health care and physical therapy. However, these services and supplies are only covered by Part B when medically necessary and prescribed by a doctor. Enrollment in Part B is optional and the Medicare recipient pays a premium of approximately \$65 per month for these added benefits. The amount of the premium is periodically adjusted. Not every person who receives Medicare Part A enrolls in Part B.

Although Medicare provides fairly broad coverage of medical treatment, neither Part A nor B pays for the cost of prescription drugs or other medications.

Medicare is funded solely by the federal government. States do not make matching contributions to the Medicare fund. Social Security contributions, monthly premiums paid by program participants, and general government revenues generate the money used to support the Medicare program. Insurance coverage provided by Medicare is similar to that provided by private health insurance carriers. Medicare usually pays 50–80% of the medical bill, while the recipient pays the remaining balance for services provided.

### Normal results

As the population of the United States ages, concerns about health care and the financing of quality health care for all members of the elderly population grow. One concern is that health insurance provided by the Medicare program will become obsolete or will be cut from the federal budget in an attempt to save money. Another concern is that money provided by the Social Security Administration for Medicare will be depleted before the aging population of the United States can actually benefit from the taxes they are now paying. A third concern is coverage for prescription medications.

During the Clinton administration, several initiatives were started that saved funds for Medicare. The DHHS also supports several initiatives to save and improve the program. However, continuance of the federal health insurance program is still a problem that American citizens expect legislators to resolve.

During the George W. Bush administration, there has been debate concerning coverage for prescription drugs. Health-care reformers suggest that prescription drugs be made available through the Medicare program due to the high cost of such medications. This debate has not been resolved as of early 2003, and legislation has not been enacted.

Some of the successful initiatives undertaken since 1992 include:

- Fighting fraud and abuse. Much attention has focused on Medicare abuse, fraud, and waste. As a result, overpayments were stopped, fraud was decreased, and abuse was investigated. This has saved the Medicare program approximately \$500 million per year.
- Preserving the Medicare benefit. Due to aggressive action by the federal government, it is estimated that funds have been appropriated to keep Medicare viable through 2026.
- Supporting Preventive Medicine and the Healthy Aging Project. Medicare programs are supporting preventive medicine and diagnostic treatments in anticipation that preventive measures will improve the health of older Americans and thereby reduce health-care costs.

Medicare benefits and health care financing are major issues in the United States. Legislators and federal agencies continue to work on initiatives that will keep health-care programs in place and working for the good of American citizens.

## Medication Monitoring

### Definition

Medication monitoring is the process of monitoring prescription medications to check that blood levels are within the expected and desired range, or the process of measuring the effects of a prescription medication in the blood.

### Description

Medication monitoring is done by measuring blood levels of a drug or some aspect of a drug's effects. Some prescription drugs are very beneficial for health and may even be life saving, yet are very dangerous if even a small overdose is given. Because of this danger, drugs that are associated with severe or life threatening medical effects after a small overdose would not be available for use in medicine without a method by which to monitor their blood levels or their effects. Medication monitoring is a critical tool in the administration of these medications.

### Therapeutic Index of Medications

All drugs may be dangerous if taken in great enough quantity. However for some drugs, the difference between a therapeutic dose and a dangerous or poisonous dose is smaller than others. The figurative "distance" between a medically effective and safe dose of a medication and its toxic dose is known as the therapeutic index or therapeutic window. Drugs with

wide therapeutic windows require a greatly increased dose before they are toxic and are therefore safer to use than drugs with narrow therapeutic windows. Drugs with narrow therapeutic windows have a smaller difference in dose amount between their beneficial and harmful effects. If the therapeutic index of a drug is small enough, that drug may require medication monitoring techniques to be added as part of the treatment regimen to ensure that it is used safely.

### Monitoring the Effects of Anticoagulants

**Anticoagulant drugs** are administered to inhibit the ability of the blood to form a blood clot, a process known as blood coagulation. Anticoagulants are not administered to dissolve existing blood clots, but rather to prevent the clotting process from forming a new blood clot or increasing an existing one. The most common health condition that may require anticoagulation drug therapy is a cardiac arrhythmia (abnormal heart rhythm) called atrial fibrillation. Atrial fibrillation is a rapid arrhythmia in a portion of the heart known as the atria, that may lead to a stroke. A stroke is a condition involving the inability of blood vessels in the brain to provide oxygen to brain tissue. A stroke may be caused by a blood clot blocking the blood vessel that supplies a part of the brain, thereby depriving the brain of oxygen and causing **death** of brain tissue. In atrial fibrillation, blood clots are sometimes knocked off of the heart tissue and travel through the blood to the brain, causing a stroke. Anticoagulant therapy may prevent a stroke by preventing the formation of blood clots. It may also prevent blood clots that could damage heart tissue or lead to a heart attack. The anticoagulant drug warfarin (coumadin) is most commonly used for this purpose.

While anticoagulant drugs have great benefit for prevention of stroke in atrial fibrillation, they can also be very dangerous. If the blood is kept too "thin" (via a decreased ability to clot), small wounds or a bump on the head may cause life threatening internal bleeding. Under normal conditions, these minor injuries would not cause excessive bleeding because the blood would clot and close the wound. With too great a dose of warfarin, minor injuries may become catastrophes. Even without injury, dangerous internal bleeding such as gastrointestinal bleeding or brain hemorrhages may occur. For this reason, the amount of warfarin given must only be the minimum necessary for treatment.

There is no one dose of warfarin that is safe and standardized for all patients. It must be individually determined, and the amount that is necessary may change frequently even within an individual. The effects of warfarin must be monitored at least weekly

## QUESTIONS TO ASK YOUR DOCTOR

- Which of my medications needs to be routinely monitored?
- Why does this medication require monitoring?
- Why is this medication the best treatment option for my health condition?
- What are the effects of too much of this medication?
- How often do I need to come have my blood levels checked?
- Is the drug being measured in my blood, or an effect of the drug?

to ensure that too much has not been given (avoiding dangerous blood conditions) or that too little has been given to provide the therapeutic effect. Warfarin is not directly measured from blood samples, but rather the blood is examined for the degree of change in its blood clotting mechanisms. By measuring the effect of warfarin on the blood, doses can be tailored up or down to maintain a therapeutic but safe level. There is a very narrow window in which warfarin's effects are desirable, and it is very close to dangerous doses. Without medication monitoring techniques, warfarin could not be used to save lives in patients with heart conditions.

### Monitoring Anticonvulsant Drugs

Anticonvulsant drugs are used to treat epilepsy, a type of neurological seizure disorder. The goal of anticonvulsant therapy is to provide seizure prevention without causing too many adverse side effects of drug treatment. Anticonvulsants such as phenytoin (dilantin) are beneficial for seizure patients, but also have a relatively narrow therapeutic index. Additionally, there is great variability in the way different patients metabolize the drug. Studies have shown that different patients taking the same dose of phenytoin may have up to a 50-fold difference in blood levels. There is also variability in the amount of drug needed to control seizure disorders in different patients within a safe range of doses. For all these reasons, there is no one dose that is standardized for all patients. Rather, the dose used for each patient varies widely, and needs to be individually tailored and monitored. The level of phenytoin may be directly measured in blood serum to make sure that blood levels are within the therapeutic range, and that they are not toxic levels. If blood levels of phenytoin are below what is considered a therapeutic range, doses

## KEY TERMS

**Atria**—Plural for atrium.

**Atrial Fibrillation**—A dangerous heart condition involving a rapid, irregular heartbeat.

**Atrium**—Chamber of the heart that contains specialized heart cells that set the heartbeat.

**Blood Serum**—The fluid portion of the blood.

**Cardiac Arrhythmia**—An irregular heartbeat.

**Coagulation**—Blood clotting.

**Epilepsy**—A neurological disorder that involves uncontrolled seizures.

**Gastrointestinal Tract**—The path in the body from the mouth, through the stomach, intestines, rectum, and the anus.

**Phlebitis**—Inflammation of a vein.

**Stroke**—An event causing impairment of blood circulation to the brain, causing death of brain tissue and potentially drastically affecting mental functioning.

are usually increased within safe limits even if the patient has not been experiencing seizures since initiating therapy.

Anticonvulsant drugs may be monitored when a patient first starts the drug to make sure they reach therapeutic levels, after a patient has been on the drug to make sure they are maintaining therapeutic and not toxic levels, or to explore symptoms of toxicity that may potentially be caused by the drug. Anticonvulsant drugs may also be monitored when the patient is experiencing seizures despite drug therapy. If levels of the current anticonvulsant are within the established therapeutic range of doses, then there may be need to assess whether to add other medications to the treatment regimen or switch to another medication entirely.

### Risks of Medication Monitoring

There is very little risk associated with having blood drawn for medication monitoring. Most people have no side effects or a small bruise. However, with any blood draw there is a small chance that the area around the punctured vein may develop phlebitis, the inflammation of a vein. Phlebitis may also involve a bacterial infection if the site of the blood draw was not appropriately cleaned before the needle was inserted. Phlebitis can be locally painful but usually resolves in a short period of time.

## Meningocele repair

### Definition

A meningocele repair is a surgical procedure performed to repair an abnormal opening in the spinal column (called spina bifida) by draining excess fluid and closing the opening.

### Purpose

The surgery is necessary to close this abnormal opening in order to decrease the risk of infection and protect the integrity of the spinal column and the tissue inside.

### Demographics

According to the Spina Bifida Association of America, spina bifida is both the most common neural tube defect and the most common birth defect resulting in permanent disability. It is estimated that about 40% of Americans have spina bifida occulta. However, some people who have it may have no symptoms and may therefore be unaware of their condition, so the percentage is an approximation. Meningocele and myelomeningocele are noticeable at birth and are paired together as spina bifida manifesta. Spina bifida manifesta occurs in about one in 1,000 births, with 4–5% occurring as meningocele and 95–96% occurring as myelomeningocele.

## KEY TERMS

**Folic acid**—A water-soluble vitamin belonging to the B-complex group of vitamins.

**Meninges**—The membrane covering neural tissue.

**Shunt**—A shunt is a tube that is used to drain excess fluid. It is surgically implanted. The shunt drains the fluid from around the brain and sends it into the abdomen.

### Description

The term meningocele may be used to refer to more than one condition. Spina bifida is a neural tube birth defect involving an abnormal opening in the spine. It occurs when the fetus's spine does not close properly during the first month of fetal development. In spina bifida occulta an opening in the spinal bones exists, but the neural tissue and membrane covering the spine (the meninges) are not exposed. Because there is no opening, the defect may appear as a dimple, or depression, at the base of the spine (the sacrum). Another sign of spina bifida occulta is the presence of tufts of hair at the sacrum. It is possible that while there is no opening, vertebrae are missing and there is damage to nerve tissue.

A meningocele is a sac protruding from the spinal column, which contains some of the spinal fluid and meninges. The sac may be covered with skin or with the meninges, and does not contain neural tissue. It may be located near the brain or along the spinal column. Hydrocephalus is rarely present, and the neurological examination may be normal. Because the neural tissue remains intact, it can be repaired by the experienced neurosurgeon, with excellent results.

A myelomeningocele is the most severe type of spina bifida because the spinal cord has herniated into the protruding sac. Neural tissue and nerves may be exposed. About 80% of myelomeningoceles occur at the lower back, where the lumbar and sacral regions join. Some people refer to myelomeningocele as spina bifida. Because of the exposed neural tissue, significant symptoms may be present. These symptoms may include:

- muscle weakness or paralysis in the hips and lower limbs
- no sensation in the part of the body below the defect
- lack of bowel and bladder function
- fluid build-up in the brain, known as hydrocephalus

Because of the risk of neural tissue damage, swelling, and infection into the spinal fluid and brain with an opening in the spinal column, surgery to repair the meningocele or myelomeningocele is usually done within 24 hours of birth. However, although the opening is closed, whatever damage has already been done to the neural tissue is permanent. If hydrocephalus is developing, the meningocele repair may be done first. Then, a few days later, a shunt can be inserted to resolve the hydrocephalus. If the hydrocephalus is present at birth, the two surgeries may be done at the same time to decrease the risks associated with increasing pressure on the brain. To prevent drying of the sac, it may be kept moist with sterile **dressings** until surgery is begun. Once the anesthesia has put the baby to sleep and the surgery is pain-free, a surgical incision is made into the sac. Excess fluid is drained, and the meninges is wrapped around the spine to protect it. The opening is then closed with sutures.

### Diagnosis/Preparation

If an individual has spina bifida occulta, with no outward signs of a neural tube defect and no symptoms, the condition may go undetected. The protruding sacs associated with meningocele and myelomeningocele are quite noticeable at birth. To understand the extent of the defect x rays, **ultrasound**, computed tomography (CT) scans, or **magnetic resonance imaging** (MRI) of the spine may be taken.

Spina bifida may be diagnosed while the mother is still pregnant, through prenatal screening. If spina bifida is indicated, a blood test will show an elevated alpha fetoprotein. However, elevated levels can be present without spina bifida, so further testing should be done if the test is positive. There is an elevated alpha fetoprotein level in about 85% of women with a fetus with spina bifida. An ultrasound can reliably reveal the spinal structure of the fetus. An **amniocentesis** may be done to check for chromosomal abnormalities. In amniocentesis, a long syringe is used to draw amniotic fluid out from the uterus through the mother's abdomen. Because the protruding sac of the meningocele and myelomeningocele can look the same on the outside, it is important to have a clear diagnosis, as the anticipated outcome of the two conditions is very different.

### Aftercare

The infant will first spend some time in the **recovery room**, and then be transferred to an **intensive care unit**. The infant will be monitored for signs of excess bleeding and infection. Temperature will be closely monitored. **Antibiotics** will be given to decrease the

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

Surgery on the spine is a very delicate procedure and needs to be done by a surgeon specializing in pediatric neurosurgery. It is best performed in a hospital with a pediatric intensive care unit available to closely monitor the infant after the surgery.

risk of infection, and the infant will be positioned to lie flat on the stomach to avoid pressure on the surgical wound. Extreme care is taken to keep the wound clean of urine and stool.

### Risks

Surgical risks include infection and bleeding. Anesthesia risks include a reaction to the medications used, including difficulty breathing. During meningocele and myelomeningocele repair, there are additional risks of damage to the spinal column and infection of the spinal fluid surrounding the spine and brain. Damage to the neural tissue could result in paralysis, or loss of nerve function (for example, loss of bowel and bladder control). There may also be an increased risk of an urinary tract infection. An infection of the meninges is called meningitis. However, further damage would be expected if surgery were not done, and serious infection would be likely. As in all surgery, one must weigh the potential risks against the expected benefits.

### Normal results

Results depend greatly on the extent of involvement of exposed neural tissue and the condition of the infant prior to surgery. A meningocele repair can have excellent results, as neural tissue does not extend into the protruding sac. In myelomeningocele, the amount of exposed neural tissue will determine the extent of lower limb weakness, or paralysis. The infant will usually spend a few weeks in the hospital after surgery before being able to be discharged home. As the child grows, it may be necessary to use braces, crutches, or a wheelchair for mobility. If surgery for hydrocephalus is successful, the prognosis is better. Children with a repaired myelomeningocele may be able to go to school, but will benefit from special education and associated services. There may be varying degrees of learning problems, and difficulties with the child's attention span. An effective bowel and bladder-training program can help make attending school easier. Because of muscle

## QUESTIONS TO ASK THE DOCTOR

- What is the extent of the neurological damage?
- Is my child likely to walk?
- What experience do you have with this procedure?
- What complications have your patients experienced with this procedure?
- How long is my child likely to stay in the hospital?

weakness or paralysis, a child with spina bifida will need physical therapy and may require future surgeries.

### Morbidity and mortality rates

With current medical and surgical treatments, about 85% of infants survive, and about 50% will be able to walk. Bowel and bladder disorders contribute significantly to morbidity and mortality in those with spina bifida who survive past the age of two years.

### Alternatives

There is no alternative to surgical repair. Risk of infection and damage to the spine and brain is high with an opening to the spine, so surgery is necessary to close the opening and drain the excess fluid that could put pressure on the brain. The Spina Bifida Association of America recommends that all women of child-bearing age take 0.4 mg of folic acid daily, as this amount has been shown to decrease the likelihood of neural tube defects. Once a woman is aware of being pregnant, the critical first month of neural tube development has already past, and folic acid cannot cure any damage that has been done.

## Mental health assessment

### Definition

A mental health assessment is an examination used to ascertain whether or not a patient is functioning on a healthy psychological, social, or developmental level. A mental health assessment can also be used to aid diagnosis of some neurological disorders, specific diseases, or possible drug abuse.

### Purpose

Mental health assessments are performed to screen for mental health disorders such as depression or anxiety, or as part of their continuing evaluation. They can also be used to help diagnose neurological pathology, such as Alzheimer's disease. A mental health assessment may be indicated if a person is having difficulty at work, school, or in social situations. For example, a diagnosis of Attention Deficit Hyperactivity Disorder (ADHD) or a personality disorder may begin with a mental health assessment as part of their discovery. Mental health assessments may also be done if substance abuse is suspected.

### Demographics

A mental health assessment can be done for patients of any age or gender. The mental health assessment of a child or adolescent is based on developmental stage as appropriate for age. An adult mental health assessment may be done to screen for new diagnoses, assess patients with an existing diagnosis for changes in severity, or to assess the need to modify current a treatment plan.

(Mikael Karlsson / Alamy)

## WHO PERFORMS THE PROCEDURE?

A general practitioner may perform a brief mental health assessment during a routine examination. However, if there are symptoms of a mental disorder present, the patient may be referred to a specialist for a more thorough mental health assessment. A specialist for a mental health assessment may be a psychologist or a psychiatrist.

A psychologist is a health care professional who is not a medical doctor. A psychologist may have a degree called a PsyD (doctor of psychology), or a PhD (doctor of philosophy) in psychology. Psychologists can evaluate and counsel patients, and need to be licensed to practice. However in most states, psychologists cannot prescribe medication.

A psychiatrist is a medical doctor who specializes in the diagnosis and treatment of mental health problems. Psychiatrists can evaluate, counsel, and prescribe medications to treat mental health problems. Some psychiatrists further specialize in specific areas of mental health, such as psychiatry for adolescents. Psychiatrists need to be licensed to practice. They should be board-certified through the Board of Psychiatry and Neurology, a board that is validated by the American Board of Medical Specialties.

## Description

### *Patient History*

History taking is an important component of the mental health assessment. The **health history** of a patient includes their medical health history, family health history, medications they are currently on, and social history. Social history is a critical component, including history of drug use, physical or emotional abuse, and exposure to traumatic situations. It also covers the “chief complaint,” or description of the patient’s current issue in the context of the patient’s life, both past and present. Health care professionals who perform a mental health assessment need to obtain a thorough health history from the patient, because it places the current situation into the context of the patient’s overall health. For the current chief complaint, the health care provider will ask questions to form an overall picture of how the patient is feeling and any distressing emotions the patient is experiencing. A pertinent health history also includes information on

## QUESTIONS TO ASK YOUR DOCTOR

- Why do I need a mental health assessment?
- Who will perform the assessment?
- How will the assessment be performed?
- How long is the assessment expected to take?
- What tests are involved in my mental health assessment?
- Are there any specific preparations I need to make before or after the assessment?
- What will the results of the assessment specifically indicate?
- When will the results be available?
- What are the risks of the assessment?
- Who else has access to the results of the assessment?
- Do any of my prescription medications, non-prescription medications, nutritional, or herbal supplements potentially affect the results of my mental health assessment?

any previous psychiatric illness, for both the patient and the patient’s family. It is important that the health care provider be made aware of not only current prescription medications, but also non-prescription medications, nutritional supplements, and herbal supplements or teas the patient is currently taking, as they may affect the patient’s mental status. History of suicide attempts or thoughts may be initially discussed during the history portion of the assessment.

### *Mental Status Examination*

The mental status examination explores multiple aspects of the patient’s ability to function in a healthy, normal manner. The health care provider will assess the multiple components of the patient’s mental status through both direct questioning and objective observation.

**GENERAL APPEARANCE.** General appearance is assessed by observation on the part of the health care provider. Patient hygiene, grooming, excessive nervousness or physical activity, and apparent nutritional state are all pertinent to the mental status examination. General alertness, facial expressions, and eye contact are noted. The patient’s attitude toward the health care provider is also an important component, including whether the patient seems hostile, guarded, friendly, or cooperative.

## KEY TERMS

**Affect**—The external manifestation of a mood or state of mind. Affect is usually observed in facial expression or other body language.

**Attention Deficit Hyperactivity Disorder (ADHD)**—A disorder involving a developmentally inappropriate degree of inattention and impulsivity. Hyperactivity may or may not be a component. This disorder usually appears in childhood and manifests itself as difficulty at home or school. It sometimes persists into adulthood where it may affect work, relationships, and other social situations.

**Alzheimer's Disease**—A disease of the elderly involving progressive mental deterioration including loss of memory, judgment, and intellect; disorientation; confusion; general inability to mentally function in social situations. The disease may begin as early as late mid-life and results in eventual death. It is associated with specific physical changes to the brain that can be visualized using medical imaging techniques.

**Autism**—A childhood disorder that manifests as an inability to communicate with or relate to others, or interact in social situations in a healthy, normal manner. Autism may range from mild to severe and includes repetitive behaviors, the inability to cope with changes from routine activities, and obsessions with specific objects. Autism is sometimes associated with below-normal intelligence or anxiety.

**Brain Lesion**—Physical damage done to a specific part or location of the brain, that may result in

specific symptoms or behaviors associated with that brain lesion.

**Chemical Toxicity**—State of physical illness induced by poisoning with toxic chemicals. Chemical toxicities may affect a person's behavior or mental function.

**Cognition**—The mental activity of thinking, learning, and memory.

**Compulsion**—The uncontrollable impulse to perform specific acts. In mental health disorders, compulsions are often repetitive and carried out by the person in order to avoid feelings of anxiety.

**Computed Tomography (CT scan)**—A computer uses x-rays across many different directions on a given cross section of the body, and combines all the cross sections to create one image. CT scans can be used to visualize bodily organs including the brain, blood vessels, bones, and the spinal cord. Contrast dye is sometimes administered to the patient to help visualize structures.

**Delusion**—Conviction of a false belief or wrong judgment despite obvious evidence to the contrary.

**Dementia**—The progressive loss of cognitive and intellectual function of the brain including impaired memory, judgment, and disorientation, without the impairment of perception or consciousness. It is usually associated with a structural brain disease such as Alzheimer's disease.

**Developmental Disorder**—A disorder or disability that occurs because of prenatal or early childhood

**MOOD AND AFFECT.** Mood is the internal set of sustained emotions that the patient experiences, while affect is the external manifestation of mood as body language and facial expression. Patients are questioned as to what moods they have experienced for lengths of time, such as depression, tiredness, or anxiety. Affect may be described as normal; blunted or flat where the patient has little expression; expansive and inappropriate where the patient seems to be experiencing extremes of emotion that may not be appropriate to the setting.

**SPEECH AND THOUGHT PROCESSES.** Speech is examined for clarity, general coherence, appropriate inflection (not monotone), quantity that is unusually large or small, a rate that is unusually fast or slow, and appropriate volume. While asking questions during the examination, the health care provider will also monitor

the responses given by the patient for specific thought processes or patterns of speech. The following examples may be observed by the health care provider or described by the patient: flight of ideas where the patient randomly changes from one topic to another; looseness of association where the patient makes irrelevant connections between seemingly unrelated topics; racing thoughts; excessively trailing off onto tangents; nonsensical speech; rhyming or creation of new words; halting speech; paucity of speech; or speaking in riddles.

**THOUGHT CONTENT.** Thought content may be evaluated through both direct questioning and observation of topics brought up by the patient. There are many types of thought content that may be pertinent to this section of the mental health assessment. Thought aspects of mental disorders may include the following: hallucinations that may be auditory, visual,

events that affect cognition, language, motor, or social skills.

**Flight of Ideas**—A psychiatric term describing a thought disorder where streams of unrelated words or ideas enter a patient's mind too quickly to be properly vocalized despite the rushed and rapid rate of the patient's speech.

**Hallucination**—The perception of a person, object, event, or sensory stimulus that is not truly there. Hallucinations can be visual (seen), auditory (heard), olfactory (smelled), tactile (felt), gustatory (tasted), or a combination thereof.

**Looseness of Association**—A psychiatric term describing a thought disorder where a patient makes irrelevant connections between seemingly unrelated topics. In a mental health assessment the patient's responses may not seem to correspond to the question asked by the health care provider.

**Magnetic Resonance Imaging (MRI)**—A diagnostic test where a magnetic field is applied to atoms within a patient's body, aligns the atoms, and reads the energy pulses given off by the atoms in a manner that creates a three-dimensional picture of the patient's internal structures. There is no exposure to radiation. An MRI is especially useful for visualizing soft tissue and for neurological imaging.

**Metabolic Disturbance**—A disturbance in the general function of the body's basic life processes such as energy production. The body's ability to provide

the brain with appropriate nourishment can affect the mental status of the individual.

**Obsession**—A recurrent and persistent idea, thought, or impulse that the individual cannot repress.

**Parkinson's Disease**—A neurological disease resulting from a deficiency of the neurotransmitter dopamine that is associated with specific recognizable movements, affects, and behavior patterns.

**Personality Disorder**—Group of behavioral disorders characterized by maladaptive patterns of behavior, social interactions, or lifestyles that deviate from the healthy normal. Personality disorders are distinct from psychotic disorders.

**Phobia**—An irrational and unfounded fear of a situation, place, or object that causes a state of panic.

**Psychiatrist**—A medical doctor (MD) who specializes in the treatment of mental health problems and can prescribe medication.

**Psychologist**—A health care professional (PsyD or PhD) who is not a medical doctor but can evaluate or provide counseling for patients with mental health issues.

**Thyroid Dysfunction**—A physical state that involves the failure of the thyroid gland to function properly. Thyroid dysfunction not only affects a person's physical state, but may have secondary effects on their mental state as well.

tactile, or olfactory; auditory hallucinations involving commands for the patient to carry out specific actions; delusions of having special powers, status, or persecution by others; paranoid thinking; obsessions, compulsions, and ritualistic behaviors; phobias; thoughts of self-harm or suicide; homicidal thoughts.

**COGNITION.** An important aspect of the mental status examination is assessment of the patient's cognitive state. Elements of this section include the following: assessment of general awareness and level of consciousness; orientation to person, current location, current date and time, and situation; ability to pay attention and concentrate; general memory tests; ability to follow directions; language comprehension and appropriate usage of language; ability to perform abstract reasoning by interpreting proverbs supplied by the health care provider.

### *Written and Verbal Tests*

Written or verbal tests are used as part of a mental health assessment when there is a reason to apply the test to explore a specific potential diagnosis. There are standardized tests for many different mental disorders and disturbances. For example, depression is sometimes assessed using a specific set of standards or measurements called a rating scale. Other tests may evaluate intelligence levels, and aid in the diagnosis of dementia or developmental disorders such as learning disabilities or autism. These types of tests are controversial and do not stand alone to make a diagnosis, but rather may be used in addition to the other components of the mental health assessment. Each test may take from thirty minutes to several hours to complete, and be may administered over multiple days.

### Adjunctive Tests

**PHYSICAL EXAMINATION.** Mental health assessments are sometimes helpful in diagnosing certain neurological disorders, and may be performed in the larger context of a neurological examination. The neurological examination includes a mental status exam, as well as assessing motor function, reflexes, sensory perception, posture, and gait. Diseases such as Parkinson's disease or Alzheimer's disease may initially be suspected as a result of the mental health assessment.

**CLINICAL TESTS.** Clinical tests may be necessary as an adjunct to the mental health assessment, to aid in diagnosis of specific neurological or neuropsychiatric disorders. For example, a patient with Alzheimer's disease may require **Magnetic Resonance Imaging (MRI)** as an adjunct to the mental health assessment for a successful diagnosis. Clinical tests may also be used rule out non-mental health related illnesses. Some drugs of abuse, thyroid dysfunction, hormonal imbalances, prescription medications, chemical toxicities, metabolic disturbances, selective brain lesions, or types of tumors may all manifest in ways that affect the mental status assessment. Blood laboratory testing, Computed Tomography (CT scan), or an MRI may help to assess the presence or absence of these physical states.

### Follow-up after the Assessment

Whether or not a patient requires further inpatient care, outpatient care, or medication is dependent upon the final diagnosis. Inpatient care is always indicated if the patients are unable to suitably care for themselves, suicidal, or homicidal.

### Risks

The mental health assessment is a valuable tool in the diagnosis of mental health problems. However, some mental health problems are very difficult to diagnose. Mental health assessments may need to be performed multiple times before any medical conclusion is reached. Even with multiple mental health assessments and adjunctive tests, there is risk that an accurate diagnosis may still be missed.

Maria Basile, PhD

## Mentoplasty

### Definition

Mentoplasty is a term that refers to **plastic surgery** procedures for the chin. It comes from the Latin word *mentum*, which means chin, and the Greek verb *plassein*, which means "to form" or "to shape." Mentoplasty is also known as genioplasty or chinplasty.

### Purpose

Mentoplasty may be done for several reasons:

- To correct malformations of the chin resulting from developmental abnormalities of the bones in the jaw. Sometimes the jawbones continue to grow on one side of the face but not the other, leading to facial asymmetry. In other instances a part of the jawbone is missing; this condition is known as congenital agenesis of the jaw.
- To reshape a chin that is out of proportion to other facial features.
- As part of gender reassignment surgery. The size and shape of the chin and lower jawline are somewhat different in men and women. Some people choose to have mentoplasty as part of their gender transition.
- As part of craniofacial reconstruction following trauma or cancer surgery.
- As part of orthognathic surgery. Orthognathic surgery involves repositioning the facial bones in order to correct deformities that affect the patient's ability to speak or chew normally.

## KEY TERMS

**Aesthetic**—Pertaining to beauty. Plastic surgery done to improve the patient's appearance is sometimes called aesthetic surgery.

**Agensis**—The absence of an organ or body part due to developmental failure.

**Alloplast**—An implant made of an inert foreign material such as silicone or hydroxyapatite.

**Congenital**—Present at the time of birth.

**Extrusion**—Pushing out or expulsion. Extrusion of a chin implant is one possible complication of mentoplasty.

**Genioplasty**—Another word for mentoplasty. It comes from the Greek word for "chin."

**Hematoma**—A localized collection of blood in an organ or tissue due to broken blood vessels.

**Intraoral**—Inside the mouth.

**Malocclusion**—Malpositioning and defective contact between opposing teeth in the upper and lower jaws.

**Microgenia**—An extremely small chin. It is the most common deformity of the chin.

**Orthognathic surgery**—Surgery that corrects deformities or malpositioning of the bones in the jaw. The term comes from two Greek words meaning straight and jaw.

**Sliding genioplasty**—A complex plastic surgery procedure in which the patient's jawbone is cut, moved forward or backward, and repositioned with metal plates and screws.

**Submental**—Underneath the chin.

Insurance coverage for mentoplasty depends on its purpose. Chin reshaping that is done to improve personal appearance is not usually covered by insurance. Mentoplasty that is performed as a reconstructive procedure after trauma, genetic deformity, or orthognathic surgery may be covered by insurance.

The cost of mentoplasty varies considerably according to the complexity of the procedure. The average surgeon's fee for a chin implant was \$1,612 in 2002. The average fee for a sliding genioplasty, however, was \$4,000–\$6,000.

## Demographics

In spite of the fact that chin deformities are the most common facial abnormality, mentoplasty is not

one of the more frequently performed procedures in plastic surgery. In 2002, there were 18,352 mentoplasties performed in the United States, compared to 117,831 face lifts and 282,876 liposuctions. Most mentoplasties are done in combination with rhinoplasties.

Mentoplasty is primarily performed in adult patients; it is not usually done in children until all permanent teeth have come in and the jaw is close to its adult size. According to the American Society of Plastic Surgeons, 7% of patients who had mentoplasties in the United States in 2002 were 18 or younger; 35% were between the ages of 19 and 34; 40% were between the ages of 35 and 50, while another 15% were between 51 and 64. Only 3% were over 65.

With respect to sex, women account for 69% of mentoplasty patients; only 31% are men.

## Description

Mentoplasties fall into two large categories: procedures that augment (increase) small or receding chins; and those that reduce large or protruding chins. Chin augmentation is done more frequently than chin reduction, reflecting the fact that microgenia (small chin) is the most common abnormality of the chin.

### Chin augmentation

Chin augmentation can be performed by inserting an implant under the skin of the chin or by performing a sliding genioplasty. Insertion of an implant takes 30–60 minutes, while a sliding genioplasty takes slightly longer, 45–90 minutes. If the mentoplasty is done together with orthognathic surgery, the operation may take as long as three hours.

Chin implants are used in patients with mild or moderate microgenia. At one time they were made of cartilage taken from donors or from other sites on the patient's body, but as of 2003 alloplastic implants (made from inert foreign materials) are used more often because they reduce the risk of infection. To insert the implant, the surgeon can choose to make the incision under the chin (submental) or inside the mouth (intraoral). In either case, the surgeon cuts through several layers of tissue, taking care to avoid damaging the major nerve in the chin. The surgeon makes a pocket in the connective tissue inside the chin and washes it out with an antiseptic solution. The sterile implant is then inserted in the pocket and positioned properly. The incision is closed and the wound covered with Steri-Strips.

A sliding genioplasty may be performed if the patient's chin is too small for augmentation with an

implant, or if the deformity is more complex. In this procedure, the surgeon cuts through the jawbone with an oscillating saw and removes part of the bone. He or she then moves the bone segment forward, holding it in place with metal plates and screws. After the bone segment has been fixed in place, the incision is closed and the patient's head is wrapped with a pressure dressing.

### *Chin reduction*

Reduction of an overly large or protruding chin may be done either by direct reduction or a sliding genioplasty. In a direct reduction, the surgeon makes either a submental or an intraoral incision and removes excess bone from the chin with a burr. A sliding genioplasty reduction is similar to a genioplasty to augment the chin, except that the bone segment is moved backward rather than forward.

## Diagnosis/Preparation

### *Diagnosis*

Diagnostic evaluation consists of a facial analysis as well as a complete dental and medical history. The chin is one of the three most significant parts of the face from an aesthetic standpoint, the others being the forehead and the nose. Many patients who are concerned about the size of their nose, for example, can be helped by having a too-small chin augmented as well as having the nose reshaped. In the facial analysis, the face is divided into thirds, with the mouth and chin in the lowest third. The surgeon compares the proportions of the features in each third in order to determine the most suitable procedure for restoring balance. The patient will be photographed from several angles to document the condition of the chin before surgery.

The dental history and x-ray studies of the head and jaw are necessary in order to determine whether the facial disproportion can be corrected by an implant or simple reduction, or whether orthognathic surgery is required. Patients who have severe malocclusion (irregular contact between the teeth in the upper and lower jaws) or deformities of the facial bones are usually referred to a maxillofacial specialist for **reconstructive surgery**.

Lastly, the surgeon will evaluate the patient for any signs of psychological instability, including unrealistic expectations of the results of surgery.

### *Preparation*

Patients should stop smoking and discontinue all medications containing **aspirin** or NSAIDs for two

weeks prior to mentoplasty. If the surgeon is planning to make a submental incision, the patient should use an antibacterial facial cleanser for two days before surgery. Patients scheduled for an intraoral approach should rinse the mouth with mouthwash three times a day for two days before surgery. They should not eat or drink anything for eight hours prior to the procedure.

## Aftercare

Patients should have someone drive them home after the procedure. They are given medication for discomfort and a one-week course of antibiotic medication to reduce the risk of infection. Most patients can return to work in seven to 10 days.

Other aspects of aftercare include the following:

- a soft or liquid diet for four to five days
- raising the head of the bed or using two to three pillows
- rinsing the mouth with a solution of hydrogen peroxide and warm water two to three times daily
- avoiding sleeping on the face and unnecessary touching of the chin area
- avoiding vigorous physical exercise for about two weeks

## Risks

In addition to infection, bleeding, and an allergic reaction to the anesthetic, the risks of insertion of a chin implant include:

- deformity of the chin following an infection
- injury to the major nerve in the chin, leading to loss of feeling or paralysis of the chin muscles
- erosion of the bone beneath the implant
- moving around or dislocation of the implant
- extrusion (pushing out) of the implant

Specific risks associated with sliding genioplasties include:

- under- or overcorrection of the defect
- injury to the major nerve in the chin
- failure of the bone segment to reunite properly with the other parts of the jaw
- damage to the roots of the teeth
- hematoma (a collection of blood within a body organ or tissue caused by leakage from broken blood vessels; it can damage the results of a mentoplasty by causing pressure that distorts the final shape of the chin)

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

Mentoplasties may be performed by plastic surgeons, oral surgeons, or maxillofacial surgeons. Fat injections and facial liposuction are usually performed by plastic surgeons.

Chin implant insertions or direct reductions are usually performed as outpatient procedures in the surgeon's office or an ambulatory surgery center. The patient may be given either general or local anesthesia. Sliding genioplasties can be done as outpatient procedures; however, they are usually performed in hospitals under general anesthesia, particularly if the patient is having orthognathic surgery at the same time.

### Normal results

Normal results of either augmentation or reduction mentoplasty include correction of facial asymmetry and disproportion. The functioning of the jaw is also often improved. Patients who have had a mentoplasty are usually very satisfied with the results.

### Morbidity and mortality rates

The rate of complications with chin implants as well as sliding genioplasties is about 5%.

### Alternatives

#### *Fat injections*

In some cases, fat may be injected into the area below the chin to plump up the skin and minimize the apparent size of the chin. This technique, however, is limited to minor disproportions of chin size. In addition, fat injections must be repeated periodically as the fat is gradually absorbed by the body.

#### *Liposuction*

Facial **liposuction** can be used together with or instead of mentoplasty to improve the patient's profile. In particular, removal of fatty tissue below the chin can make a receding chin look larger or more prominent.

## QUESTIONS TO ASK THE DOCTOR

- Would you recommend a chin implant or a sliding genioplasty in my case?
- Would you use a submental or an intraoral approach to a chin augmentation?
- How many mentoplasties have you performed?
- Should I consider a mentoplasty in combination with another facial procedure?

## Microsurgery

### Definition

Microsurgery is surgery that is performed on very small structures, such as blood vessels and nerves, with specialized instruments under a microscope.

### Purpose

Microsurgical procedures are performed on parts of the body that are best visualized under a microscope. Examples of such structures are small blood vessels, nerves, and tubes. Microsurgery uses techniques that have been performed by surgeons since the early twentieth century, such as blood vessel repair and organ transplantation, but under conditions that make traditional **vascular surgery** difficult or impossible.

The first microvascular surgery, using a microscope to aid in the repair of blood vessels, was described by Jules Jacobson of the University of Vermont in 1960. The first successful replantation (reattachment of an

## KEY TERMS

**Capillaries**—Tiny blood vessels that deliver oxygen to tissues.

**Peripheral nerves**—The nerves outside of the brain and spinal cord.

**Vascular surgery**—A branch of medicine that deals with the surgical repair of disorders of or injuries to the blood vessels.

**Venous valves**—Folds on the inner lining of the veins that prevent the backflow of blood.

amputated body part) was reported in 1964 by Harry Bunke. This replantation of a rabbit's ear was significant because blood vessels smaller than 0.04 inch (1 mm)—similar in size to the blood vessels found in a human hand—were successfully attached. Two years later, the successful replantation of a toe to the hand of a monkey was made possible using microsurgical techniques. Soon thereafter, microsurgery began being used in a number of clinical settings.

Numerous surgical specialties utilize the techniques of microsurgery. Otolaryngologists (ear, nose, and throat doctors) perform microsurgery on the small, delicate structures of the inner ear or the vocal cords. Cataracts are removed by ophthalmologists (eye doctors), who also perform corneal transplants and treat eye conditions like glaucoma. Urologists can reverse vasectomies (male sterilization), and gynecologists can reverse tubal ligations (female sterilization), giving people new choices about having children. Microsurgical techniques are used by plastic surgeons to reconstruct damaged or disfigured skin, muscles, or other tissues, or to transplant tissues from other parts of the body. And, importantly, a number of specialties can collaborate to treat patients who have limbs or other body parts; under certain circumstances, amputated parts can be reattached, or another body part can be replanted in the place of one lost (for example, a great toe replacing a lost or damaged thumb).

Today, microsurgery can be lifesaving. Neurosurgeons can treat vascular abnormalities found in the brain, and cancerous tumors can be removed.

### Description

#### Equipment

Microsurgical equipment magnifies the operating field, provide instrumentation precise enough to

maneuver under high magnification, and allow the surgeon to operate on structures barely visible to the human eye. The most important tools used by the microsurgeon are the microscope, microsurgical instruments, and microsuture materials.

**MICROSCOPE.** While operating microscopes may differ according to their specific use, certain features are standard. The microscope may be floor- or ceiling-mounted, with a moveable arm that allows the surgeon to manipulate the microscope's position. A view of the surgical site is afforded by a set of lenses and a high-intensity light source. This lighting is enhanced by maintaining a low level of light in the rest of the **operating room**. Two or more sets of lenses allow a surgeon and an assistant to view the operating field and focus and zoom independently. A video camera allows the rest of the **surgical team** to view the operating field on a display screen. Features that come on some microscopes include foot and/or mouth switch controls and motorized zoom and focus.

A magnification of five to forty times (5–40x) is generally required for microsurgery. A lower magnification may be used to identify and expose structures, while a higher magnification is most often used for microsurgical repair. Alternatively, surgical loupes (magnifying lenses mounted on a pair of eyeglasses) may be used for lower magnifications (2–6x).

**INSTRUMENTS.** Microsurgical instruments differ from conventional instruments in a number of ways. They must be capable of delicately manipulating structures barely visible to the naked eye, but with handles large enough to hold comfortably and securely. They must also take into account the tremor of the surgeon's hand, greatly amplified under magnification.

Some of the various instruments that are used in microsurgery include:

- forceps
- needle holders (for suturing)
- scissors
- vascular clamps (for controlling bleeding) and clamp applicators
- irrigators (for washing structures in the surgical field)
- vessel dilators (for opening up the cut end of a blood vessel)
- various standard surgical tools

**SUTURE MATERIALS.** Suturing, or stitching, is done by means of specialized thread and needles. The diameter (gauge) of suture thread ranges in size and depends on the procedure and tissue to be sutured. Conventional suturing usually requires gauges of 2-0 (0.3 mm) to 6-0 (0.07 mm). Conversely, gauges of 9-0

(0.03 mm) to 12-0 (0.001 mm) are generally used for microsurgery. Suture thread may be absorbable (able to be broken down in the body after a definite amount of time) or non-absorbable (retaining its strength indefinitely), natural (made of silk, gut, linen, or other natural material) or synthetic (made of nylon, polyester, wire, or other man-made material). The type of suture thread used depends on the procedure and tissue to be sutured.

The suture needle comes in various sizes (diameters and length) and shapes (straight or curved), and also with different point types (rounded, cutting, or blunt). It comes with suture thread preattached to one end; this is called the swage. As in the case of suture thread, the type of needle used depends on the procedure and tissue to be sutured; generally, needles with a diameter of less than 0.15 mm are used for microsurgery.

### Training

For a surgeon to perform microsurgery in a clinical setting, extensive training and practice are required. A basic knowledge of anatomy and surgical techniques is essential. After a thorough introduction to the operating microscope and other microsurgical equipment, basic techniques are introduced using small animals as the experimental model. Specifically, surgeons must be taught how to maintain correct posture and to maintain constant visual contact with the microscope during surgery, how to properly hold and use the instruments, how to minimize the amount of hand tremor, and how to perform basic techniques, such as suturing. After becoming proficient at these skills, more advanced techniques can be taught, including procedures regarding how to treat specific conditions.

Extensive and ongoing practice is necessary for a surgeon to maintain adequate proficiency at microsurgical techniques. For this reason, a microsurgical laboratory is made available to surgeons for training and practice.

### Techniques

Most microsurgical procedures utilize a set of basic techniques that must be mastered by the surgeon. These include blood vessel repair, vein grafting, and nerve repair and grafting.

**BLOOD VESSEL REPAIR.** Blood vessel, or vascular anastomosis, is the connection of two cut or separate blood vessels to form a continuous channel. Anastomoses may be end-to-end (between two cut ends of a blood vessel) or end-to-side (a connection of one cut end of a blood vessel to the wall of another vessel).

The first step of creating an anastomosis is to identify and expose the blood vessel by isolating it from surrounding tissues. Each end of the vessel is irrigated (washed) and secured with clamps for the duration of the procedure. A piece of contrast material is placed behind the surgical site so that the tiny vessel can be more easily visualized. The magnification is then increased for the next segment of surgery. The first suture is placed through the full thickness of the vessel wall; the second and third sutures are then placed at 120° from the first. Subsequent sutures are placed evenly in the remaining spaces. Arteries 1 millimeter in diameter generally require between five and eight **stitches** around the perimeter, and veins of the same size between seven and 10. Once the last suture has been placed, the clamps are released and blood is allowed to flow through the anastomosis. If excessive bleeding occurs between the stitches, the vessel is reclamped and additional sutures are placed.

The procedure for an end-to-side anastomosis is similar, except that an oval-shaped hole is cut in the wall of the recipient vessel. Sutures are first placed at each of the oval to connect the attaching vessel to the recipient vessel, and then placed evenly to fill in the remaining spaces.

**VEIN GRAFTING.** Vein grafting is an alternative procedure to end-to-end anastomosis and may be pursued if cut ends of a blood vessel cannot be attached without tension. Nonessential veins similar in diameter to the recipient blood vessel can be removed from the hand, arm, or foot. If the graft is to be used to reconstruct an artery, its direction is reversed so that the venous valves do not interfere with blood flow. End-to-end anastomosis is then performed on each end of the graft, using the suture techniques described above.

**NERVE REPAIR.** The process of connecting two cut ends of a nerve is called neurorrhaphy, or nerve anastomosis. Peripheral nerves are composed of bunches of nerve fibers called fascicles that are enclosed by a layer called the perineurium; the epineurium is the outer layer of the nerve that encases the fascicles. Nerve repair may involve suturing of the epineurium only, the perineurium only, or through both layers.

Many of the techniques used for blood vessel anastomoses are also used for nerves. The cut ends of the nerve are exposed, then isolated from surrounding tissues. The ends are trimmed so that healthy nerve tissue is exposed, and a piece of contrast material placed behind the nerve for better visualization. Each nerve end is examined to determine the pattern of fascicles; the nerve ends are then rotated so that the fascicle patterns align. Sutures may be placed around

the circumference of the epineurium; this is called epineurial neurorrhaphy. The perineurium of each cut fascicle end may be stitched with excess epineurium removed (perineurial neurorrhaphy), or both layers may be sutured (epiperineurial neurorrhaphy).

**NERVE GRAFTING.** If there is a large gap between the cut ends of a nerve, neurorrhaphy cannot be performed without creating tension in the nerve, which can interfere with postsurgical function. A piece of nerve from another part of body may be used to create a nerve graft, which is stitched into place using anastomosis techniques. A disadvantage to nerve grafting is that a loss of function or sensation is experienced from the donor nerve site. A common nerve used for grafting is the sural nerve, which innervates parts of the lower leg.

### Diagnosis/Preparation

In an emergency situation, such as an **amputation** or crushing injury, a number of steps must be taken immediately to improve the odds that replantation or reconstruction will be successful. An IV line is placed so that fluids and **antibiotics** can be administered. The injured area is x rayed so that the extent of the injury can be determined, and the amputated body part is wrapped in sterile gauze and placed on ice, so that the tissues are preserved. To prevent freezing, the body part must not be packed below the ice. The patient is transported by ambulance or helicopter to the nearest surgical center capable of microsurgical repair.

In other cases, a patient may suffer from a chronic condition or wound, and microsurgery can be scheduled as an elective procedure. Prior to surgery, the patient will be instructed to refrain from tobacco use because it interferes with healing. In addition, the patient will be told not to eat after midnight the day of surgery. It is important that the patient inform the doctor completely about any prior surgeries, medical conditions, or medications taken on a regular basis, including **nonsteroidal anti-inflammatory drugs** (NSAIDs), such as **aspirin**. Patients taking blood thinners, such as Coumadin or Heparin (generic name: warfarin), should not adjust their medication themselves, but should speak with their prescribing doctors regarding their upcoming surgery). Patients should never adjust dosage without their doctors' approval. This is especially important for elderly patients, asthmatics, those with hypertension, or those who are on ACE inhibitors.

The patient will be placed under **general anesthesia** for the duration of the procedure. The advantages to general anesthesia are that the patient remains

unconscious and completely relaxed during the procedure, imperative because of the precise nature and extended duration of the surgery. The patient must be able to tolerate the long surgery and therefore must be relatively stable condition; complex surgeries may take up to 12 hours or more.

Microsurgery makes possible a number of reconstructive procedures that would be more difficult or impossible with conventional surgery. Some of the more frequently performed microsurgical procedures include:

- **Replantation.** This emergency surgery is performed to reattach an amputated body part such as a finger, arm, or foot. Replantation surgery requires a series of time- and energy-intensive steps to reattach all of the structures while the amputated part is still viable. The cut bone must be shortened slightly so that blood vessels and nerves can be reattached without tension. Anastomoses are created between cut arteries and veins and blood flow is reestablished to the amputated part. Tendons (if present) are then repaired, followed by nerves and soft tissues. Further procedures may be necessary to completely the reconstruction depending on the extent of the injury.
- **Transplantation.** In some cases an amputated part cannot be reattached, or tissue is deformed because of a congenital defect or an injury. Transplantation may then be an option. The great toe or second toe may be removed from a patient's foot and transplanted to the hand to replace a missing finger. A segment of rib along with its blood supply can be used to reconstruct bones in the face and jaw.
- **Free-tissue transfers.** Also called free flaps, free-tissue transfers may be used to reconstruct damaged tissues that cannot be treated with skin grafts, closed by traditional methods such as suturing, or allowed to heal without intervention. This includes tissues that have constricted after a burn, injuries in which there is not sufficient skin to properly close the wound, or tissues that have been removed as a result of treatment for cancer. Examples of tissues that may be transferred with microsurgical techniques are skin, muscle, fat, bone, and intestine.

### Aftercare

Following surgery, the patient is given intravenous fluids and usually progresses to a liquid diet within 12 to 24 hours, and a regular diet soon thereafter. The patient must be kept warm and adequately hydrated, and the surgical site is elevated if possible to help drain excess fluids. Medications are administered to help manage pain. The color, temperature, quality of capillary refill,

and tissue turgor (fullness) of the surgical site are closely monitored. Skin should be pink, warm, and have one- to two-second capillary refill. Conversely, tissue that is pale or blue, cool, with no refill or rapid refill may indicate a problem with blood flow.

Certain tests may be recommended to further evaluate the surgical site. These include:

- **Doppler ultrasound.** This technology uses high-frequency sound waves to evaluate the flow of blood to and from the surgical site.
- **Intravenous fluorescein.** After a chemical dye called fluorescein is administered to the patient, a specialized machine called a fluorimeter is used to determine how much blood is flowing through the surgical site.
- **Pulse oximetry.** A pulse oximeter measures the amount of oxygen in the blood and tracks the patient's pulse.
- **Arteriography.** X rays are taken of the surgical site after a contrast dye has been injected into the bloodstream to determine the condition of vascular anastomoses.

When the patient is discharged from the hospital, he or she will receive instructions for aftercare. Exposure to tobacco must be limited for at least six weeks following the surgery, as nicotine interferes with circulation. The patient must remain warm as **body temperature** also affects circulation. Bed rest may be prescribed for a period of days to weeks after surgery, depending on the procedure. Patients who have had a hand, finger, or multiple fingers replanted must keep the part elevated at heart level to help blood flow and decrease swelling.

Some form of rehabilitation is often recommended after microsurgery. This includes a program of individualized exercises used to restore function to a replanted or transplanted body part. In some cases where problems with circulation occur after surgery, leech therapy may be recommended. Leeches are worms that attach to the skin and draw blood while also injecting substances into the skin that act as a local anesthetic and an anticoagulant (preventing the formation of blood clots). Therapy involves attaching a leech to the replanted part or tissue flap and allow it to feed for 15 to 30 minutes, several times a day, until blood flow is established.

## Minimally invasive heart surgery

### Definition

Minimally invasive heart surgery refers to surgery performed on the beating heart to provide coronary artery bypass grafting. This technique is often referred to as MIDCAB, minimally invasive direct coronary artery bypass; or OPCAB, off-pump CABG.

### Purpose

Minimally invasive heart surgery is performed on the diseased heart to reroute blood around clogged arteries and improve the blood and oxygen supply to the heart. This approach provides patients some benefit in that cardiopulmonary bypass (use of a heart-lung machine) may be avoided. In addition, smaller incisions can be used instead of the standard sternotomy (incision through the sternum, or breastbone) approach. Faster recovery time, decreased procedure costs, and reduced morbidity and mortality are the goals of this technique.

Minimally invasive technique is not new to the field of cardiac surgery. It was performed as early as the 1950s, although the technology associated with

**In traditional open heart surgery, a large incision is made in the chest, and the sternum must be broken (A). Minimally invasive surgery uses a much smaller incision between the ribs to access the heart (B).** (Illustration by GGS Information Services. Cengage Learning, Gale.)

stabilizing the cardiac structure during the procedure has become more sophisticated. Also, the anesthesiologist and perfusionist (person monitoring blood flow) have developed better techniques to preserve cardiac function during the procedure to help the surgeon achieve the desired outcome. During the 1990s these new techniques were named: off-pump CABG

## KEY TERMS

**Anastomosis**—Connection of the bypassing blood vessel to the blocked blood vessel by surgical suture. The stitches may be made in continuous manner or individual, with continuous being more common. The disadvantage of continuous suture can be purse-stringing or cinching of the graft opening during knotting of the suture.

**Angiography**—Injecting dye into blood vessels so they can be seen on an x ray.

**Arrhythmia**—Cardiac electrical signaling that generates an ECG rhythm other than normal sinus rhythm.

**Balloon angioplasty**—A procedure used to open an obstructed blood vessel. A small, balloon-tipped catheter is inserted into the vessel and the balloon is inflated to widen the vessel and push the obstructing material against the vessel's walls. The result is improved blood flow through the vessel.

**Cannula**—A small, flexible tube.

**Cardioplegic arrest**—Halting the electrical activity of the heart by delivery of a high potassium solution to the coronary arteries. The arrested heart provides a superior surgical field for operation.

**Cardiopulmonary bypass**—Use of the heart-lung machine to provide systemic circulation cardiac output and ventilation of the blood.

**Coronary occlusion**—Obstruction of an artery that supplies the heart. When the artery is completely blocked, a myocardial infarction (heart attack) results; an incomplete blockage may result in angina.

**Coronary stent**—An artificial support device used to keep a coronary vessel open.

**Electrocardiography**—A testing technique used to measure electrical impulses from the heart in order to gain information about its structure or function.

**Myocardial infarction**—Heart attack.

**Stabilizer**—A device used to depress the movement of the area around the coronary artery where the anastomosis is made. The stabilizer is used to provide a still, motionless field for suturing.

**Sternotomy**—A surgical opening into the thoracic cavity through the sternum (breastbone).

**Thoracotomy**—A surgical opening into the thoracic cavity.

(OPCAB) and minimally invasive direct coronary artery bypass (MIDCAB). The MIDCAB procedure includes procedures done both with and without cardiopulmonary bypass, the later being referred to as off-pump MIDCAB. Unless otherwise specified, MIDCAB refers to both types of procedures.

Minimally invasive valve surgery has been an outgrowth of the success with minimally invasive coronary artery bypass grafting. Incisions other than the traditional sternotomy allow access to the heart. Minimally invasive valve surgery still requires cardiopulmonary bypass, since this is a true open-heart procedure (i.e. this is not surgery that is done while the heart is beating). New tools in managing cardioplegic cardiac arrest allow for the smaller incision unobstructed by the required instrumentation. Cannulation of the femoral vessels instead of the larger vessels of the heart also improves visualization.

### Demographics

Patients under the age of 70, but not limited by age, with a history of coronary artery disease can be evaluated for this procedure. High risk patients with advanced age, at risk for stroke, or suffering peripheral

vascular disease, renal disease, or with poor lung function may benefit from OPCAB and MIDCAB.

Typically, disease of the left anterior descending coronary artery is treated with the technique called off-pump MIDCAB. With sternotomy, disease of the right and left coronary arteries can also be addressed by OPCAB. The significance and location of the coronary artery lesions may limit the success of the MIDCAB or OPCAB procedure. Most practices have at least one surgeon skilled in performing revascularizations without cardiopulmonary bypass. Of all coronary artery bypass grafting procedures, approximately 10–20% are performed in this manner.

### Description

The patient receives cardiac monitoring during **general anesthesia**. Systemic anticoagulation is given to avoid clot formation from foreign surfaces and any periods of artery blockage (occlusion).

### MIDCAB

If cardiopulmonary bypass is not employed, the procedure is called an off-pump MIDCAB. The surgeon performs an alternative incision (rather than a

midline sternotomy), typically a left anterior **thoracotomy**. The left internal mammary artery is dissected from the left chest wall. A stabilizer device is placed on the heart to provide support of the left anterior descending artery as the heart continues to beat. This device applies gentle pressure or suction, mildly limiting cardiac function. The left internal mammary artery is sutured to the left anterior descending artery to bypass the blockage (anastomosis).

If cardiopulmonary bypass is indicated, the surgeon inserts cannulae (small, flexible tubes) into the femoral vessels. Aortic occlusion and cardioplegia are administered through a catheter advanced through the contralateral femoral artery into the aortic root (ascending aorta). This catheter has a balloon tip that stops blood flow to the coronary arteries when inflated, but allows selective administration of cardioplegia (a solution that stops the heart) to the coronary arteries. **Angiography** is performed to provide visualization of catheter placement.

The surgeon performs an alternative incision (rather than a midline sternotomy), typically a left anterior thoracotomy. The left internal mammary artery is dissected from the left chest wall. Cardiopulmonary bypass can be instituted with or without cardioplegic arrest. Cardioplegic arrest requires cardiopulmonary bypass. The use of cardioplegic arrest makes this a non-beating heart procedure, but it is still considered MIDCAB. Cardioplegic arrest of the heart occurs as the balloon tip of the catheter is inflated. The left internal mammary artery is sutured to the left anterior descending artery to bypass the blockage (anastomosis). Once the anastomosis is complete the balloon is deflated, allowing the heart to begin to beat. Cardiopulmonary bypass is discontinued once cardiac function is stabilized. The cannulae and catheter are removed, and the groin wounds are closed with sutures.

### **OPCAB**

The OPCAB procedure does not use cardiopulmonary bypass. The incision of choice can be a midline sternotomy or a left anterior thoracotomy (incision in the side). The midline sternotomy allows access to both the right and left internal mammary arteries. Additional vascular bypass conduits may be acquired by harvesting the saphenous vein (in the leg), gastroepiploic artery (near the stomach), or radial artery (in the arm). A stabilizing device is used to secure the coronary artery of choice. This device applies gentle pressure or suction, mildly limiting cardiac function, but providing better access to posterior and inferior vessels of the heart. The surgeon makes the necessary anastomosis to the targeted coronary arteries. If

conduits other than the mammary arteries are used they are connected to the ascending aorta to provide systemic blood flow.

If an anticoagulant was administered, drugs are given to reverse the anticoagulant. Upon completion of the off-pump MIDCAB, MIDCAB, or OPCAB procedure, the chest is closed. If a midline sternotomy was performed, stainless steel wires are implanted to hold the sternal bone together. Sutures are used to close the skin wound, and sterile **bandages** are applied as a wound dressing.

### **Diagnosis/Preparation**

An **electrocardiogram** detects the presence of acute coronary blockage (occlusion). A history of myocardial infarction can also be detected by electrocardiogram. Patients with a history of angina also are evaluated for coronary artery disease. Coronary angiography provides the best diagnostic information about the extent and location of the coronary artery disease.

### **Aftercare**

The patient receives continued cardiac monitoring in the **intensive care unit**. Once the patient is able to breathe on his/her own, the breathing tube is removed (extubation), if it is not removed immediately post-operatively. Any medications to treat poor cardiac function or manage blood pressure are discontinued as cardiac function improves and blood pressure stabilizes. Blood drainage tubes protruding from the chest cavity are removed once internal bleeding decreases. The patient also may be equipped with external cardiac pacing to maintain heart rate. The pacing is terminated once the heart is beating at an adequate rate free of arrhythmia. A warming blanket may be used to warm the patient's core temperature that was decreased by the surgical exposure.

The duration of the post-operative hospital stay is reduced by one to two days in these procedures. Pain also should be reduced. **Home care** for the wound is described prior to discharge, and instructions for responding to adverse events after discharge also are given. Patients who have undergone these procedures should expect to return to normal activities sooner than those who have undergone traditional coronary artery bypass grafting.

### **Risks**

MIDCAB can result in a higher rate of restenosis (recurrence of narrowing of the arteries) than traditional coronary artery bypass grafting, but these numbers continue to decrease as experience with the

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

Medical centers performing cardiac surgical procedures are equipped to perform this procedure. A cardiothoracic, cardiovascular, or cardiac surgeon receives additional training to successfully complete this procedure. Special technology in stabilizer design is purchased by the institution and made available for the surgeon to master. Within most clinical practices one surgeon becomes skilled in the technique. This one surgeon completes most procedures off-pump with MIDCAB or OPCAB techniques as necessary to revascularize the patient.

procedure improves. Some patients may have to have the procedure converted to a standard sternotomy with cardiopulmonary bypass, if the anastomosis can not be completed from the MIDCAB approach. Rib fracture is the most common adverse event. Pericarditis also is a possible complication. Supraventricular arrhythmias and ST segment elevation also may develop.

In the event of systemic blood pressure abnormalities, arrhythmia, poor surgical anastomosis, or poor exposure of the coronary blood vessels, OPCAB patients may require conversion to cardiopulmonary bypass for completion of the anastomosis. Post-operatively some patients may need additional surgery to control bleeding or to address poor sternal healing. This is related to the increased use of both internal mammary arteries for these procedures. Cerebral complications and atrial fibrillation also may be experienced. These post-operative complications are comparable to those seen in patients who have undergone traditional coronary artery bypass grafting.

### Normal results

Patency (openness) of the grafted vessels is expected to be the same as what is seen in traditional coronary artery bypass grafting. When compared to traditional coronary artery bypass grafting, minimally invasive heart surgery also is expected to result in a shorter hospital stay, less pain, fewer blood transfusions, and quicker return to normal activity.

### Morbidity and mortality rates

#### MIDCAB

Conversion to a full sternotomy or sternotomy with cardiopulmonary bypass is expected in 1–2% of

## QUESTIONS TO ASK THE DOCTOR

- Is there a surgeon associated with this practice skilled with OPCAB or MIDCAB procedures?
- Can the surgeon skilled in these procedures evaluate the patient for an OPCAB or MIDCAB procedure?
- How many procedures has the surgeon performed in the last year? In the last five years?
- What is the surgeon's reoperation rate in regards to length of graft patency?

patients. Redo procedures and **reoperation** can occur in over 5% of patients, which is still lower than the risk of a second procedure associated with balloon **angioplasty** and stent placement. Over 90% of all patients are expected to be free of adverse events. Complications most frequently involve rib fracture (over 10% of patients). Mortality associated with MICAB is low and is not seen during the surgical procedure in most instances, but is associated with post-operative complications.

#### OPCAB

Conversion to cardiopulmonary bypass may be required in patients if anastomosis cannot be completed due to unstable blood pressure, arrhythmia, ischemia, poor anastomosis, or poor surgical access. The same operative mortality is expected when compared to cardiopulmonary bypass patients. The expected decrease in neurological events, renal dysfunction, pulmonary complications, or arrhythmias has not yet been shown to be a consistent benefit, therefore all of these complications can still occur.

### Alternatives

Percutaneous balloon angioplasty and **coronary stenting** of the left anterior descending artery are successful alternative procedures. MIDCAB may be a preferred treatment when compared to balloon angioplasty and stenting because fewer repeat interventions are required. An additional alternative is traditional on-pump, cardiopulmonary bypass; coronary artery bypass grafting is a powerful technique with a long record of safety and effectiveness since the 1960s.

## Mitral valve repair

### Definition

Mitral valve repair is a surgical procedure used to improve the function of a stenotic (narrowed), prolapsed (slipped from its normal position), or insufficient (weakened) mitral valve of the heart.

### Purpose

The mitral valve controls the blood flow between the left atrium (upper chamber) and left ventricle (lower chamber) of the heart. When the mitral valve functions correctly, blood flows in one direction only—from the atrium to the ventricle. Then the valve becomes diseased or weakened, blood can back-flow from the ventricle to the atrium when the ventricle contracts (systole). The mitral valve also can become narrowed, preventing the flow of blood from the left atrium into the left ventricle during ventricular filling (diastole). In mitral valve prolapse, one or more of the mitral valve's cusps protrude back into the left atrium during ventricular contraction. Mitral valve repair is performed to improve the function of the diseased valve so that it correctly controls the amount and direction of blood flow.

### Demographics

Mitral valve prolapse is the most common heart valve defect. In the United States it is present in about 2–6% of the population. The defect is believed to have an inherited component and is seen twice as often in women as in men. Having this condition does not automatically mean that mitral insufficiency will develop. Patients with a history of rheumatic fever, coronary artery disease, infective endocarditis, or collagen vascular disease also may develop mitral insufficiency.

Mitral valve stenosis almost always is the result of having rheumatic fever in childhood. Rheumatic fever

occurs in some people after a group A streptococcal throat infection (commonly called strep throat). Genetics appears to play a role in determining who develops rheumatic fever after a strep infection, with women more likely than men to progress to the disease. After rheumatic fever subsides, there is usually a latency period of 10–20 years before symptoms of mitral valve stenosis appear. The prevalence of mitral valve stenosis has declined in the United States because there has been a decline in the number of cases of rheumatic fever. In the United States in 2005, about one case of rheumatic fever occurred for every 100,000 people. Rheumatic fever is much more common in developing countries (100–150 cases per 100,000 in India, for example), and thus the rate of mitral valve stenosis is also higher. Mitral valve stenosis may be present at birth (congenital); however, it rarely occurs alone but rather in conjunction with other heart defects.

### Description

Mitral valve repair is done under **general anesthesia** with continuous cardiac monitoring. Uncomplicated mitral valve surgery normally takes 2–3 hours. In traditional mitral repair, the surgeon uses a sternotomy to access the heart and large blood vessels. Anticoagulation drugs are given as cannulae are inserted into the large veins. Cardiopulmonary bypass (use of a heart-lung machine) is instituted. The heart-beat is stopped as blood vessels are clamped to prevent blood flow through the heart. The surgeon opens the heart to see the mitral valve. He/she may expose the mitral valve by opening the right atrium and then opening the atrial septum (tissue dividing the atria). Another approach requires a large left atrium that can be opened directly, making the mitral valve visible.

### *Mitral commissurotomy*

Mitral commissurotomy is used to repair mitral stenosis associated with rheumatic fever. The commissures—openings between the valve leaflets—are manually separated by the surgeon. Fused chordae tendineae (cords of connective tissue that connect the mitral valve to the papillary muscle of the heart's left ventricle) are separated, along with papillary muscles. Calcium deposits may be removed from the valve leaflets. The left atrial appendage is removed to reduce the risk of future thromboemboli (blood clot) generation.

### *Chordae tendineae repair*

The chordae tendineae can become lengthened or rupture, resulting in mitral valve prolapse (the valve slipping out of place). A skilled surgeon repairs the mitral valve structure by placing sutures in the valve

During a mitral valve repair, the patient's chest is opened along the sternum (A). The heart is connected to a heart-lung machine, and an incision is made into the right atrium, or upper chamber of the heart (B), exposing the mitral valve (C). A section of the valve is removed, and the area is repaired with sutures (D and E). A flexible fabric ring may be stitched to the outside of the valve to strengthen it, in a procedure called an annuloplasty (F). (Illustration by GGS Information Services. Cengage Learning, Gale.)

leaflets to stabilize the valve structure. Typically the posterior leaflet requires this type of repair.

#### ***Annuloplasty***

A flexible fabric ring is sutured to the valve annulus to provide support and reconstruction for the

patient's valve annulus. The size of the ring is selected to match the patient's own valve size. This repair allows the valve to function normally.

The heart is closed with sutures. De-airing of the heart is performed before removal of the clamps. When the clamps are removed, de-airing continues to

## KEY TERMS

**Acute**—Rapid onset.

**Annulus**—A ring-shaped structure.

**Anticoagulants**—Drugs that are given to slow blood clot formation.

**Atrium (plural Atria)**—The right or left upper chamber of the heart.

**Cannula (plural cannulae)**—A small, flexible tube.

**Cardiac catheterization**—A diagnostic procedure (using a catheter inserted through a vein and threaded through the circulatory system to the heart) which does a comprehensive examination of how the heart and its blood vessels function.

**Cardiopulmonary bypass**—Use of the heart-lung machine to provide systemic circulation cardiac output and ventilation of the blood.

**Chordae tendineae**—The strands of connective tissue that connect the mitral valve to the papillary muscle of the heart's left ventricle.

**Chronic**—Long-term.

**Commissures**—The normal separations between the valve leaflets.

**Doppler echocardiography**—A testing technique that uses Doppler ultrasound technology to evaluate the pattern and direction of blood flow in the heart.

**Endocarditis**—Infection of the heart endocardium tissue, the inner most tissue and structures of the heart.

**NYHA heart failure classification**—A classification system for heart failure developed by the New York Heart Association. It includes the following four categories: I, symptoms with more than ordinary activity; II, symptoms with ordinary activity; III, symptoms with minimal activity; IV, symptoms at rest.

**Rheumatic carditis**—Inflammation of the heart muscle associated with acute rheumatic fever.

**Rheumatic fever**—An inflammatory disease that arises as a complication of untreated or inadequately treated strep throat infection. Rheumatic fever can seriously damage the heart valves.

**Sternotomy**—A surgical opening into the thoracic cavity through the sternum (breastbone).

**Systemic circulation**—Circulation supplied by the aorta including all tissue and organ beds, except the alveolar sacs of the lungs used for gas exchange and respiration.

**Thromboemboli**—Blood clots that develop in the circulation and lodge in capillary beds of tissues and organs.

**Transesophageal echocardiography**—A diagnostic test using an ultrasound device that is passed into the esophagus of the patient to create a clear image of the heart muscle and other parts of the heart.

ensure that no air enters the systemic circulation. At this time a transesophageal echocardiogram (TEE) may be used to test that the valve is functioning correctly and that the heart is free of air. If the surgeon is not satisfied with the repair, **mitral valve replacement** is performed. Once the surgeon is satisfied that the valve is working correctly, cardiopulmonary bypass is terminated, anticoagulation is reversed, and the cannulae are removed from the blood vessels. The sternotomy is closed. Permanent stainless steel wires are used to hold the sternum bone together. The skin incision is closed with sutures, and sterile **bandages** are applied to the wound.

#### *Minimally invasive mitral valve repair*

In the mid-2000s, some cardiac surgery centers began performing robot-assisted minimally invasive mitral valve repair. In minimally invasive repair, a 2–3 inch (5–8 cm) opening is made in the side of the chest instead of reaching the heart by breaking the sternum.

Then, with the assistance of a robotic arm, the valve is repaired. Minimally invasive mitral valve repair may not be appropriate for all patients, but when it is, it offers the advantages of less chance of infection and blood loss, a shorter hospital stay, and a faster, less painful recovery.

### Diagnosis/Preparation

Mitral valve stenosis is diagnosed by history, **physical examination**, listening to the sounds of the heart (cardiac auscultation), **chest x ray**, and ECG. Patients may have no symptoms of a valve disorder or may have shortness of breath (dyspnea), fatigue, or pulmonary edema (fluid in the lungs). Other patients present with atrial fibrillation (a cardiac arrhythmia) or an embolic event (result of a blood clot, i.e., heart attack or stroke). Doppler **echocardiography** is the preferred diagnostic tool for evaluation of mitral valve stenosis, and can be performed in conjunction

with non-invasive **exercise** testing by treadmill or bicycle. **Cardiac catheterization** is reserved for patients who demonstrate discrepancies in Doppler testing. Both left- and right-heart catheterization should be performed in the presence of elevated pulmonary artery pressures.

A diagnosis of mitral insufficiency requires a detailed patient history. Listening to the heart (auscultation) reveals the presence of a third heart sound. Chest x ray and ECG provide additional information. Again, Doppler echocardiography provides valuable information. Exercise testing with Doppler echocardiography can show the true severity of the disease.

After initial findings, patients may be followed with repeat visits and testing to monitor disease progress. If the patient has reached NYHA Class III or IV, replacement is considered. Severe pulmonary hypertension with pulmonary artery systolic pressures greater than 60 mm Hg is considered an indication for surgery. Left ventricular ejection fraction less than 60% also is an indication for surgery.

### Aftercare

The patient receives continued cardiac monitoring in the **intensive care unit** and usually remains in intensive care for 24–48 hours after surgery. Ventilation support is discontinued when the patient is able to breathe on his/her own. If mechanical circulatory support and inotropic drugs (substances that stimulate heart muscle contractions, e.g. digitalis) were needed during the surgical procedure, they are discontinued as cardiac function recovers. Tubes draining blood from the chest cavity are removed as bleeding from the surgical procedure decreases. Prophylactic **antibiotics** are given to prevent infective endocarditis and prevent the recurrence of rheumatic carditis.

If the patient recovers normally, **discharge from the hospital** occurs within a week of surgery. At discharge, the patient is given specific instructions about **wound care** and infection recognition, as well as contact information for the physician and guidelines about when a visit to the emergency room is indicated. Within three to four weeks after discharge, the patient is seen for a follow-up office visit with the physician, at which time physical status will have improved for evaluation. Thereafter, asymptomatic, uncomplicated patients are seen at yearly intervals. Few limitations are placed on patient activity once recovery is complete.

### Risks

There are always risks associated with general anesthesia and cardiopulmonary bypass. Risks specifically

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

Cardiothoracic and cardiovascular surgeons perform mitral valve repair. Surgeons are trained during their residency to perform these procedures, although a certain level of skill is required for perfection of the technique. Medical centers that perform cardiac surgery are able to provide mitral valve repair.

associated with mitral valve repair include embolism, bleeding, or operative valvular endocarditis. When valve repair does not produce adequate results, then increased operative time is required to replace the mitral valve. If the patient's mitral valve is replaced with a mechanical valve, the patient must take an anticoagulation drug, such as Coumadin, for the rest of his/her life. An inadequately repaired valve, if left untreated, results in continued myocardial dysfunction resulting in pulmonary edema, congestive heart failure, and systemic thromboemboli generation.

### Normal results

Patients treated by mitral valve repair for mitral insufficiency can expect improved myocardial function and relief of symptoms. Oxygen consumption by skeletal muscle continues to improve. Cardiac output improves and pulmonary hypertension resolves over several months after the initial decrease in left atrial pressure, pulmonary artery pressure, and pulmonary arteriolar resistance.

Excellent results in terms of improved cardiac function and symptom relief also are expected for patients that undergo mitral valve repair for mitral stenosis.

### Morbidity and mortality rates

Operative mortality associated with mitral valve repair for stenosis is 1–3%. The prognosis for restenosis (re-narrowing) is 30% at five years and 60% at nine years; additional surgery is required in 4–7% of patients at five years. Eighty to 90% of patients whose mitral valve stenosis was repaired by commissurotomy are complication free at five years after surgery.

Mitral valve repair for mitral insufficiency is the preferred approach because it preserves the valvular apparatus and left ventricular function. It also eliminates the risk of mechanical valve failure and the need for lifelong anticoagulation.

## QUESTIONS TO ASK THE DOCTOR

- Is mitral valve repair the best treatment choice for my condition?
- Am I a candidate for minimally invasive mitral valve repair?
- How many of these procedures has the surgeon performed in the last year? in the last five years?
- What is the surgeon's morbidity and mortality rate with mitral valve repair?
- What will happen if the repair fails?
- What type of follow-up care is required during the first year after surgery and throughout the rest of my life?
- What type of complications can be encountered both acute and chronic?

### Alternatives

The asymptomatic patient with a history of rheumatic fever can be treated with prophylactic antibiotics and followed until symptoms appear. If atrial fibrillation develops antiarrhythmic medications can be used for treatment. Atrial **defibrillation** may relieve atrial fibrillation. Anticoagulants may be prescribed to prevent the occurrence of systemic embolization.

Mitral valve repair for mitral regurgitation is not as successful if the anterior leaflet is involved. Rheumatic, ischemic, or calcific diseases decrease the likelihood of repair in even the most skilled hands. In the absence of mitral valve replacement, mitral valve repair is indicated.

## Mitral valve replacement

### Definition

Mitral valve replacement is surgical procedure in which the diseased mitral valve of the heart is replaced by a mechanical valve or biological tissue valve.

### Purpose

The mitral valve controls the blood flow between the left atrium (upper chamber) and left ventricle (lower chamber) of the heart. When the mitral valve functions correctly, blood flows in one direction only—from the atrium to the ventricle. When the valve becomes diseased or weakened, blood can back-flow from the ventricle to the atrium when the ventricle contracts (systole). The mitral valve also can become narrowed, preventing the flow of blood from the left atrium into the left ventricle during ventricular filling (diastole). In mitral valve prolapse, one or more of the mitral valve's cusps protrude back into the left atrium during ventricular contraction. **Mitral valve repair** is the preferred operation to correct these conditions and improve the function of the diseased valve so that it correctly controls the amount and direction of blood flow. When mitral valve repair is not possible, mitral valve replacement is performed. The defective mitral valve is surgically removed and a new mechanical valve or biological tissue valve (from a pig, cow, or human cadaver) is put into place to correctly control blood flow.

### Demographics

Mitral valve prolapse is the most common heart valve defect. In the United States it is present in about 2–6% of the population. The defect is believed to have an inherited component and is seen twice as often in women as in men. Having this condition does not

## KEY TERMS

**Annulus**—A ring-shaped structure.

**Anticoagulants**—Drugs that are given to slow blood clot formation.

**Biological tissue valve**—An autograft is a valve that comes from the patient, usually the pulmonary valve. An autologous pericardial valve is constructed from the patient's pericardium (the fibrous sac that surrounds the heart and the roots of the great vessels and also forms the outer layer of the heart wall) at the time of surgery. A homograft (or allograft) valve is a valve harvested from a human cadaver. A porcine (pig) or bovine (cow) heterograft is animal tissue valve that is made acceptable to the body by destroying antigenicity so that the body will not reject the foreign tissue.

**Cardiac catheterization**—A diagnostic procedure (using a catheter inserted through a vein and threaded through the circulatory system to the heart) which does a comprehensive examination of how the heart and its blood vessels function.

**Cardiopulmonary bypass**—Use of the heart-lung machine to provide systemic circulation cardiac output and ventilation of the blood.

**Doppler echocardiography**—A testing technique that uses Doppler ultrasound technology to evaluate the pattern and direction of blood flow in the heart.

**Endocarditis**—Infection of the heart endocardium tissue, the inner most tissue and structures of the heart.

**Mechanical valve**—There are three types of mechanical valve: ball valve, disk valve, and bileaflet valve.

**NYHA heart failure classification**—A classification system for heart failure developed by the New York Heart Association. It includes the following four categories: I, symptoms with more than ordinary activity; II, symptoms with ordinary activity; III, symptoms with minimal activity; IV, symptoms at rest.

**Rheumatic carditis**—Inflammation of the heart muscle associated with acute rheumatic fever.

**Rheumatic fever**—An inflammatory disease that arises as a complication of untreated or inadequately treated strep throat infection. Rheumatic fever can seriously damage the heart valves.

**Sternotomy**—A surgical opening into the thoracic cavity through the sternum (breastbone).

**Systemic circulation**—Circulation supplied by the aorta including all tissue and organ beds, except the alveolar sacs of the lungs used for gas exchange and respiration.

**Thromboemboli**—Blood clots that develop in the circulation and lodge in capillary beds of tissues and organs.

**Transesophageal echocardiography**—A diagnostic test using an ultrasound device that is passed into the esophagus of the patient to create a clear image of the heart muscle and other parts of the heart.

automatically mean that mitral insufficiency will develop, and even when it does, mitral valve repair is often preferable to valve replacement. Patients with a history of rheumatic fever, coronary artery disease, infective endocarditis, or collagen vascular disease also may develop mitral insufficiency.

Mitral valve stenosis almost always is the result of having rheumatic fever in childhood. Rheumatic fever occurs in some people after a group A streptococcal throat infection (commonly called strep throat). Genetics appears to play a role in determining who develops rheumatic fever after a strep infection, with women more likely than men to progress to the disease. After rheumatic fever subsides, there is usually a latency period of 10–20 years before symptoms of mitral valve stenosis appear. The prevalence of mitral valve stenosis has declined in the United States because there has been a decline in the number of

cases of rheumatic fever. In the United States in 2005, about one case of rheumatic fever occurred for every 100,000 people. Rheumatic fever is much more common in developing countries (100–150 cases per 100,000 in India, for example), and thus the rate of mitral valve stenosis is also higher. Mitral valve stenosis may be present at birth (congenital); however, it rarely occurs alone but rather in conjunction with other heart defects. Again, repair is preferable to replacement of the mitral valve.

### Description

A heart valve is a structure within the heart that prevents the backflow of blood by opening and closing with each heartbeat. Replacement heart valves are either mechanical or biological tissue valves. For patients under the age of 65, the mechanical valve offers superior longevity, but the use of this type of

valve requires that the patient take an anticoagulation drug for the rest of his/her life. The biological tissue valve does not require anticoagulation therapy, but this type of valve is prone to deterioration leading to re-operation after about 10–15 years. Women who may want to have children after a valve replacement should usually receive a biological tissue valve, because the anticoagulant warfarin (Coumadin) most often prescribed for patients with mechanical valves is associated with fetal birth defects. **Aspirin** can be substituted for warfarin in certain circumstances.

Mitral valve replacement is done under **general anesthesia** with continuous cardiac monitoring. Uncomplicated mitral valve surgery normally takes 2–3 hours. To replace the mitral valve, the surgeon breaks the breastbone (sternum) to gain access to the heart and large blood vessels. Anticoagulation drugs are given as cannulae are inserted into the large veins. Cardiopulmonary bypass (use of a heart-lung machine) is instituted. The heartbeat is stopped as blood vessels are clamped to prevent blood flow through the heart. The surgeon opens the heart to see the mitral valve. He/she may expose the mitral valve by opening the right atrium and then opening the atrial septum (tissue dividing the atria). Another approach requires a large left atrium that can be opened directly, making the mitral valve visible.

Next, the surgeon cuts the diseased valve away from the valve annulus (outer ring). The annulus is sized so that the proper size of valve can be selected for the patient's anatomy. Sutures are applied around the valve annulus, the valve is sutured into place, and tied into position. The atrial septum is closed with suture or left to heal naturally, and the heart is closed with sutures.

De-airing of the heart is performed before removal of the clamps. When the clamps are removed, de-airing continues to ensure that no air enters the systemic circulation. At this time a transesophageal echocardiogram (TEE) may be used to test that the valve is functioning correctly and that the heart is free of air. If the surgeon is not satisfied with the repair, mitral valve replacement is performed. Once the surgeon is satisfied that the valve is working correctly, cardiopulmonary bypass is terminated, anticoagulation is reversed, and the cannulae are removed from the blood vessels. The sternotomy is closed. Permanent stainless steel wires are used to hold the sternum bone together. The skin incision is closed with sutures, and sterile **bandages** are applied to the wound.

### Diagnosis/Preparation

Mitral valve stenosis is diagnosed by history, **physical examination**, listening to the sounds of the

heart (cardiac auscultation), **chest x ray**, and ECG. Patients may have no symptoms of a valve disorder or may have shortness of breath (dyspnea), fatigue, or frank pulmonary edema. Other patients present with atrial fibrillation (a cardiac arrhythmia) or an embolic event. Doppler **echocardiography** is the preferred diagnostic tool for evaluation of mitral valve stenosis, and it can be performed in conjunction with non-invasive **exercise** testing by treadmill or bicycle. **Cardiac catheterization** is reserved for patients who demonstrate discrepancies in Doppler testing. Both left- and right-heart catheterization should be performed in the presence of elevated pulmonary artery pressures.

A diagnosis of mitral insufficiency requires a detailed patient history. Listening to the heart (auscultation) reveals the presence of a third heart sound. Chest x ray and ECG provide additional information. Again, Doppler echocardiography provides valuable information. Exercise testing with Doppler echocardiography can show the true severity of the disease.

After initial findings, patients may be followed with repeat visits and testing to monitor disease progress. If the patient has reached NYHA Class III or IV, replacement is considered. Severe pulmonary hypertension with pulmonary artery systolic pressures greater than 60 mm Hg is considered an indication for surgery. Left ventricular ejection fraction (a measure of blood output with each heartbeat) less than 60% normal also is an indication for surgery.

### Aftercare

The patient receives continued cardiac monitoring in the **intensive care unit** and usually remains in intensive care for 24–48 hours after surgery. Ventilation support is discontinued when the patient is able to breathe on his/her own. If mechanical circulatory support and inotropic agents (a substance that influences the force of muscle contractions, e.g. digitalis) were needed during the surgical procedure, they are discontinued as cardiac function recovers. Tubes draining blood from the chest cavity are removed as bleeding from the surgical procedure decreases. Prophylactic **antibiotics** are given to prevent infective endocarditis and the recurrence of rheumatic carditis.

Both mechanical and biological tissue valves require anticoagulation therapy after surgery, and while patients are hospitalized their anticoagulant status is monitored and dosages are adjusted accordingly. Patients with biological tissue valves can discontinue anticoagulation therapy within three months of valve replacement surgery, but those with mechanical valves must take an anticoagulant (aspirin, warfarin, or a

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

Cardiothoracic and cardiovascular surgeons provide surgical treatment. Surgeons are trained during the residency to perform these procedures. Medical centers that perform cardiac surgery are able to provide mitral valve replacement.

combination of the two) for the rest of their lives. These patients are regularly monitored for INR values (a measure of the clotting potential of their blood).

If the patient recovers normally, **discharge from the hospital** occurs within a week of surgery. At discharge, the patient is given specific instructions about **wound care** and infection recognition, as well as contact information for the physician and guidelines about when a visit to the emergency room is indicated. Within three to four weeks after discharge, the patient is seen for follow-up office visit with the physician, at which time physical status will have improved for evaluation. Thereafter, asymptomatic, uncomplicated patients are seen at yearly intervals. Few limitations are placed on patient activity once recovery is complete.

### Risks

There are always risks associated with general anesthesia and cardiopulmonary bypass. Risks specifically associated with mitral valve replacement include embolism, bleeding, and operative valvular endocarditis. Hemolysis (the breakdown of red blood cells) is associated with certain types of mechanical valves, but is not a contraindication for implantation.

### Normal results

Patients treated by mitral valve replacement for mitral insufficiency can expect relief of symptoms. For patients who received mechanical valves, anticoagulation therapy is continued for life. Since thromboembolic complications are associated with initial implant of biological tissue valves, patients who received this type of valve take an anticoagulant for three months after surgery. If non-cardiac surgery or dental care is needed, the anticoagulation therapy is adjusted to prevent bleeding complications.

Patients who undergo mitral valve replacement for mitral stenosis can expect excellent improvement of symptoms. Those patients with symptoms consistent with NYHA class IV before surgery have better

## QUESTIONS TO ASK THE DOCTOR

- Is mitral valve replacement the best treatment option for my condition? Why is it preferable to mitral valve repair?
- How many of these procedures has the surgeon performed in the last year? in the last five years?
- What is the surgeon's morbidity and mortality rate with mitral valve replacement?
- What type of replacement valve, biological tissue or mechanical, is best for me?
- What are the pros and cons of each valve type?
- What type of follow-up care is required during the first year after valve implant and for the rest of my life?
- What types of complications are associated with this surgery?

outcome after mitral valve replacement compared to no treatment.

### Morbidity and mortality rates

Mitral valve replacement carries a 5% risk of **death** in young, healthy patients. With increased age, additional medical problems, or pulmonary hypertension the risk of death increases substantially. Post-replacement the five-year survival is 80%. Patients over the age of 75 have poorer outcomes when mitral valve replacement is used to treat mitral insufficiency.

### Alternatives

Mitral valve replacement is considered only after mitral valve repair has proved inadequate or inappropriate. An asymptomatic patient with a history of rheumatic fever can be treated with prophylactic antibiotics and followed until symptoms appear. If atrial fibrillation develops, drugs may be used to regulate heart rhythm. Anticoagulation therapy is employed to avoid systemic emboli during periods of atrial fibrillation.

**Modified radical mastectomy****Definition**

A surgical procedure that removes the breast, surrounding tissue, and nearby lymph nodes that are affected by cancer.

**Purpose**

The purpose for modified radical **mastectomy** is the removal of breast cancer (abnormal cells in the breast that grow rapidly and replace normal healthy tissue). Modified radical mastectomy is the most widely used surgical procedure to treat operable breast

In a modified radical mastectomy, the skin on the breast is cut open (A). The skin is pulled back, and the tumor, lymph nodes, and breast tissue is removed (B and C). The incision is closed (D). (Illustration by GGS Information Services. Cengage Learning, Gale.)

cancer. This procedure leaves a chest muscle called the pectoralis major intact. Leaving this muscle in place will provide a soft tissue covering over the chest wall and a normal-appearing junction of the shoulder with the anterior (front) chest wall. This sparing of the pectoralis major muscle will avoid a disfiguring hollow defect below the clavicle. Additionally, the purpose of modified radical mastectomy is to allow for the option of **breast reconstruction**, a procedure that is possible, if desired, due to intact muscles around the shoulder of the affected side. The modified radical mastectomy procedure involves removal of large multiple tumor growths located underneath the nipple and cancer cells on the breast margins.

### Demographics

The highest rates of breast cancer occur in Western countries (more than 100 cases per 100,000 women) and the lowest among Asian countries (10–15 cases per 100,000 women). Men can also have breast cancer, but the incidence is much less when compared to women. There is a strong genetic correlation since breast cancer is more prevalent in females who had a close relative (mother, sister, maternal aunt, or maternal grandmother) with previous breast cancer. Increased susceptibility for development of breast cancer can occur in females who never breastfed a baby, had a child after age 30, started menstrual periods very early, or experienced menopause very late.

The American Cancer Society estimated that in 2007, 240,510 new cases of breast cancer would be diagnosed in the United States and 40,460 women would die as a result of the disease. Approximately one in eight women will develop breast cancer at some point in her life. The risk of developing breast cancer increases with age: women aged 30 to 40 have a one in 252 chance of developing breast cancer; women aged 40 to 50 have a one in 68 chance; women aged 50 to 60 have a one in 35 chance; and women aged 60 to 70 have a one in 27 chance—and these statistics do not even account for genetic and environmental factors.

### Description

The surgeon's goal during this procedure is to minimize any chance of local/regional recurrence; avoid any loss of function; and maximize options for breast reconstruction. Incisions are made to avoid visibility in a low neckline dress or bathing suit. An incision in the shape of an ellipse is made. The surgeon removes the minimum amount of skin and tissue so that remaining healthy tissue can be used for possible reconstruction. Skin flaps are made carefully and as

## KEY TERMS

**Lymphatic system**—A system that filters excess tissue fluids through lymph nodes to return to the bloodstream.

thinly as possible to maximize removal of diseased breast tissues. The skin over a neighboring muscle (pectoralis major fascia) is removed, after which the surgeon focuses in the armpit (axilla, axillary) region. In this region, the surgeon carefully identifies vital anatomical structures such as blood vessels (veins, arteries) and nerves. Accidental injury to specific nerves like the medial pectoral neurovascular bundle will result in destruction of the muscles that this surgery attempts to preserve, such as the pectoralis major muscle. In the armpit region, the surgeon carefully protects the vital structures while removing cancerous tissues. After axillary surgery, breast reconstruction can be performed, if desired by the patient.

### Diagnosis/Preparation

Modified radical mastectomy is a surgical procedure to treat breast cancer. In order for this procedure to be an operable option, a definitive diagnosis of breast cancer must be established. The first clinical sign for approximately 80% of women with breast cancer is a mass (lump) located in the breast. A lump can be discovered by monthly self-examination or by a health professional who can find 10–25% of breast cancers that are missed by yearly mammograms (a low radiation x ray of the breasts). A biopsy can be performed to examine the cells from a lump that is suspicious for cancer. The diagnosis of the extent of cancer and spread to regional lymph nodes determines the treatment course (i.e., whether surgery, chemotherapy, or radiation therapy, either singly or in combinations). Staging the cancer can estimate the amount of tumor, which is important not only for diagnosis but for prognosis (statistical outcome of the disease process). Patients with a type of breast cancer called ductal carcinoma in situ (DCIS), which is a stage 0 cancer, have the best outcome (nearly all these patients are cured of breast cancer). Persons who have cancerous spread to other distant places within the body (metastases) have stage IV cancer and the worst prognosis (potential for survival). Persons affected with stage IV breast cancer have essentially no chance for cure.

Persons affected with breast cancer must undergo the staging of the cancer to determine the extent of

cancerous growth and possible spread (metastasis) to distant organs. Patients with stage 0 disease have non-invasive cancer with a very good outcome. Stages I and II are early breast cancer, without lymph node involvement (stage I) and with node positive results (stage II). Persons with stage III disease have locally advanced disease and about a 50% chance for five-year survival. Stage IV disease is the most severe since the breast cancer cells have spread through lymph nodes to distant areas and/or other organs in the body. It is very unlikely that persons with stage IV metastatic breast cancer survive 10 years after diagnosis.

It is also imperative to assess the degree of cancerous spread to lymph nodes within the armpit region. Of primary importance to stage determination and regional lymph node involvement is identification and analysis of the sentinel lymph node. The sentinel lymph node is the first lymph node to which any cancer would spread. The procedure for sentinel node biopsy involves injecting a radioactively labeled tracer (technetium 99) or a blue dye (isosulphan blue) into the tumor site. The tracer or dye will spread through the lymphatic system to the sentinel node, which should be surgically removed and examined for the presence of cancer cells. If the sentinel node and one or two other neighboring lymph nodes are negative, it is very likely that the remaining lymph nodes will not contain cancerous cells, and further surgery may not be necessary.

Once a breast lump (mass) has been identified by **mammography** or **physical examination**, the patient should undergo further evaluation to histologically (studying the cells) identify or rule out the presence of cancer cells. A procedure called fine-needle aspiration allows the clinician to extract cells directly from the lump for further evaluation. If a diagnosis cannot be established by fine-needle biopsy, the surgeon should perform an open biopsy (surgical removal of the suspicious mass). Preparation for surgery is imperative. The patient should plan for both direct care and recovery time after modified radical mastectomy. Preparation immediately prior to surgery should include no food or drink after midnight before the procedure. Post-surgical preparation should include caregivers to help with daily tasks for several days.

### Aftercare

After breast cancer surgery, women should undergo frequent testing to ensure early detection of cancer recurrence. It is recommended that annual mammograms, physical examination, or additional tests (biopsy) be performed annually. Aftercare can also include psychotherapy since mastectomy is emotionally

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

The procedure is typically performed by a surgeon who has received five years of general surgery training and additional training in the specialty of surgical oncology. A surgeon who specializes in the area has expertise in removing cancerous tissues or areas. The procedure is performed in a hospital and requires that the hospital have a surgical care unit. In the surgical care unit, the patient will be treated by a team of professionals that includes, but is not limited to, physicians, nurses, physician assistants, and medical assistants.

traumatic. Affected women may be worried or have concerns about appearance, the relationship with their sexual partner, and possible physical limitations. Community-centered support groups usually made up of former breast cancer surgery patients can be a source of emotional support after surgery. Patients may stay in the hospital for one to two days. For about five to seven days after surgery, there will be one or two drains left inside to remove any extra fluid from the area after surgery. Usually, the surgeon will prescribe medication to prevent pain. Movement restriction should be specifically discussed with the surgeon.

### Risks

There are several risks associated with modified radical mastectomy. The procedure is performed under **general anesthesia**, which itself carries risk. Women may have short-term pain and tenderness. The most frequent risk of breast cancer surgery (with extensive lymph node removal) is edema, or swelling of the arm, which is usually mild, but the presence of fluid can increase the risk of infection. Leaving some lymph nodes intact instead of removing all of them may help lessen the likelihood of swelling. Nerves in the area may be damaged. There may be numbness in the arm or difficulty moving shoulder muscles. There is also the risk of developing a lump scar (keloid) after surgery. Another risk is that surgery did not remove all the cancer cells and that further treatment may be necessary (with chemotherapy and/or radiotherapy). By far, the worst risk is recurrence of cancer. However, immediate signs of risk following surgery include fever, redness in the incision area, unusual drainage from the incision, and

## QUESTIONS TO ASK THE DOCTOR

- What is the prognosis for the stage (0, I, II, III, IV) of my type of cancer?
- Will my movement be restricted after surgery?
- What care will I need on a daily basis following surgery?
- When should we set up a follow-up consultation/examination?
- Will I require other treatment (chemotherapy and/or radiation therapy) following surgery?
- What kind of mental-health treatment should I pursue (psychotherapy, community-centered support groups, etc.) following surgery?
- What options do I have for breast reconstruction? When would that treatment begin?

increasing pain. If any of these signs develop, it is imperative to call the surgeon immediately.

### Normal results

If no complications develop, the surgical area should completely heal within three to four weeks. After mastectomy, some women may undergo breast reconstruction (which can be done during mastectomy). Recent studies have indicated that women who desire cosmetic **reconstructive surgery** have a higher quality of life and better sense of well-being than those who do not utilize this option.

### Morbidity and mortality rates

The outcome of breast cancer is very dependent of the stage at the time of diagnosis. For stage 0 disease, the five-year survival is almost 100%. For stage I (early/lymph node negative), the five-year survival is also almost 100%. For stage II (early/lymph node positive), the five-year survival decreases to 81-92%. For stage III disease (locally advanced), the five-year survival is 54-67%. For women with stage IV (metastatic) breast cancer, the five-year survival is about 20%.

Approximately 17% of patients develop lymphedema after axillary lymph node dissection, while only 3% of patients develop lymphedema after sentinel node biopsy. Five percent of women are unhappy with the cosmetic effects of the surgery.

### Alternatives

There are no real alternatives to mastectomy. Surgical requirement is clear since mastectomy is recommended for tumors with dimensions over 2 in (5 cm). Additional treatment (adjuvant) is typically recommended with chemotherapy and/or radiation therapy to destroy any remaining cancer during surgery. Modified radical mastectomy is one of the standard treatment recommendations for stage III breast cancer.

## Mohs surgery

### Definition

Mohs surgery, also called Mohs micrographic surgery, is a precise surgical technique that is used to remove all parts of cancerous skin tumors while preserving as much healthy tissue as possible.

### Purpose

Mohs surgery is used to treat cancers of the skin, such as basal cell carcinoma, squamous cell carcinoma, and melanoma.

Malignant skin tumors may occur in strange, asymmetrical shapes. The tumor may have long finger-like projections that extend across the skin (laterally) or down into the skin. Because these extensions may be composed of only a few cells, they cannot be seen or felt. Standard surgical removal (excision) may miss these cancerous cells leading to recurrence of the tumor. To assure removal of all cancerous tissue, a large piece of skin needs to be removed. This causes a cosmetically unacceptable result, especially if the cancer is located on

## KEY TERMS

**Carcinoma**—Cancer that begins in the cells that cover or line an organ.

**Fixative**—A chemical that preserves tissue without destroying or altering the structure of the cells.

**Fixed**—A term used to describe chemically preserved tissue. Fixed tissue is dead so it does not bleed or sense pain.

**Mohs excision**—Referring to the excision of one layer of tissue during Mohs surgery. Also called stage.

the face. Mohs surgery enables the surgeon to precisely excise the entire tumor without removing excessive amounts of the surrounding healthy tissue.

Mohs surgery is performed when:

- The cancer was treated previously and recurred.
- Scar tissue exists in the area of the cancer.
- The cancer is in at least one area where it is important to preserve healthy tissue for maximum functional and cosmetic result, such as on the eyelids, the nose, the ears, and the lips.
- The edges of the cancer cannot be clearly defined.
- The cancer grows rapidly or uncontrollably.

## Demographics

According to the American Cancer Society, about one million people in the United States are diagnosed with non-melanoma skin cancer every year. Another 59,940 people are diagnosed with melanoma. The two most common types of skin cancer are basal cell carcinoma and squamous cell carcinoma, with basal cell carcinoma accounting for more than 90% of all of skin cancers.

Melanoma is the most serious type of skin cancer. Each year in the United States more than 59,940 people are diagnosed with melanoma, and it is becoming more and more common, especially among Western countries. In the United States, the percentage of people who develop melanoma has more than doubled in the past 30 years.

## Description

There are two types of Mohs surgery: fresh-tissue technique and fixed-tissue technique. Of the surgeons who perform Mohs surgery, 72% use only the fresh-tissue technique. The remaining surgeons (18%) use both techniques. However, the fixed-tissue technique is

used in fewer than 5% of patients. The main difference between the two techniques is in the preparatory steps.

### *Fresh-tissue technique*

Fresh-tissue Mohs surgery is performed under **local anesthesia** for tumors of the skin. The area to be excised is cleaned with a disinfectant solution and a sterile drape is placed over the site. The surgeon may outline the tumor using a surgical marking pen, or a dye. A local anesthetic (lidocaine plus epinephrine) is injected into the area. Once the local anesthetic has taken effect, the main portion of the tumor is excised (debulked) using a spoon-shaped tool (curette). To define the area to be excised and to allow for accurate mapping of the tumor, the surgeon makes identifying marks around the lesion. These marks may be made with **stitches, staples**, fine cuts with a scalpel, or temporary tattoos. One layer of tissue is carefully excised (first Mohs excision), cut into smaller sections, and taken to the laboratory for analysis.

If cancerous cells are found in any of the tissue sections, a second layer of tissue is removed (second Mohs excision). Because only the sections that have cancerous cells are removed, healthy tissue can be spared. The entire procedure, including surgical repair of the wound, is performed in one day. Surgical repair may be performed by the Mohs surgeon, a plastic surgeon, or another specialist. In certain cases, wounds may be allowed to heal naturally.

### *Fixed-tissue technique*

With fixed-tissue Mohs surgery, the tumor is debulked, as described previously. Trichloroacetic acid is applied to the wound to control bleeding, followed by a preservative (fixative) called zinc chloride. The wound is dressed and the tissue is allowed to fix for six to 24 hours, depending on the depth of the tissue involved. This period, called the fixation period, can be painful to the patient. The first Mohs excision is performed as described; however, anesthesia is not required because the tissue is dead. If cancerous cells are found, fixative is applied to the affected area for an additional six to 24 hours. Excisions are performed in this sequential process until all cancerous tissue is removed. Surgical repair of the wound may be performed once all fixed tissue has sloughed off—usually a few days after the last excision.

## Diagnosis/Preparation

An oncologist will have diagnosed the skin cancer of the patient using standard cancer diagnostic tools, such as biopsy of the tumor.

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

Mohs surgery is performed in a hospital setting by highly trained surgeons who are specialists both in dermatology and pathology. With their extensive knowledge of the skin and unique pathologic skills, they are able to remove only diseased tissue, preserving healthy tissue and minimizing the cosmetic impact of the surgery. Only physicians who have also completed a residency in dermatology are qualified for Mohs surgical training. The surgery is very often performed on an outpatient basis, usually in one day.

To prepare for surgery, and under certain conditions (such as the location of the skin tumor or health status of the patient), **antibiotics** may be given to the patient prior to the procedure; this is known as prophylactic antibiotic treatment. Patients are encouraged to eat prior to surgery and also to bring along snacks in case the procedure become lengthy. To reduce the risk of bleeding, the use of **nonsteroidal anti-inflammatory drugs** (NSAIDs), alcohol, vitamin E, and fish oil tablets should be avoided prior to the procedure. The patient who uses over-the-counter **aspirin** or the prescription blood-thinners, brands Coumadin (warfarin, generically) and heparin, should consult with the prescribing physician before adjusting the dosage of any drug.

### Aftercare

Patients should expect to receive specific **wound care** instructions from their physician or surgeon. Generally, however, wounds that have been repaired with absorbable stitches or skin grafts should be kept covered with a bandage for one week. Wounds that have been repaired using nonabsorbable stitches should also be covered with a bandage that should be replaced daily until the stitches are removed one to two weeks later. Signs of infection (e.g., redness, pain, drainage) should be reported to the physician immediately.

### Risks

Using the fresh-tissue technique on a large tumor requires large amounts of local anesthetic that can be toxic. Complications of Mohs surgery include infection, bleeding, scarring, and nerve damage.

Tumors spread in unpredictable patterns. Sometimes a seemingly small tumor is found to be quite

## QUESTIONS TO ASK THE DOCTOR

- How long have you been performing Mohs surgery?
- Will you use the fresh-tissue or fixed-tissue technique?
- Will I have to alter the use of my current medications for this procedure?
- What will you do if you don't find the border of the cancerous lesion?
- How will the wound be repaired?
- Will I need a plastic surgeon to repair the wound?
- What is the cure rate for this type of cancer when treated by Mohs surgery?
- What is the chance that the tumor will recur?
- How often will I have follow-up appointments?

large and widespread, resulting in a much larger excision than was anticipated.

### Normal results

Most skin cancers treated by Mohs surgery are completely removed with minimal loss of normal skin.

### Morbidity and mortality rates

Mohs surgery provides high cure rates for malignant skin tumors. For instance, the five-year recurrence rate for primary basal cell carcinomas treated by Mohs surgery is about 1%. Five-year recurrence rates for other techniques are as follows: surgical excision, 10.1%; curettage and desiccation, 7.7%, radiation therapy, 8.7%, and **cryotherapy**, 7.5%. For squamous cell carcinoma treated by Mohs surgery, the five-year recurrence rate is 3.1% for lesions involving the skin and lip, 5.3% for lesions involving the ear. Other modalities have a 10.9% five-year recurrence rate for lesions involving the skin and lip, and a 18.7% five-year recurrence rate for lesions involving the ear.

### Alternatives

Mohs surgery is a specialized technique that is not indicated for the treatment of every type of skin cancer, and is most appropriately used under specific, well-defined circumstances. The majority of basal cell carcinomas can be treated with very high cure rates by standard methods, including electrodesiccation and curettage (ED&C), local excision, cryosurgery (freezing), and irradiation.

MUGA scan see **Multiple-gated acquisition (MUGA) scan**

## Multiple-gated acquisition (MUGA) scan

**Definition**

The multiple-gated acquisition (MUGA) scan, also called a cardiac blood pool study, is a non-invasive nuclear medicine test that enables clinicians to obtain information about heart muscle activity. The scan displays the distribution of a radioactive tracer in the heart. The images of the heart are obtained at intervals

throughout the cardiac cycle, and are used to calculate ejection fraction (an important measure of heart performance) and evaluate regional myocardial wall motion.

**Purpose**

A MUGA scan may be done while the patient is at rest and again with stress. The resting study is usually performed to obtain the ejection fraction of the right and left ventricles, evaluate the left ventricular regional wall motion, assess the effects of cardiotoxic drugs (i.e., chemotherapy), and differentiate the cause of shortness of breath (pulmonary vs. cardiac). Ejection fraction and wall motion are also important measurements made during a stress study, but the stress study is performed primarily to detect coronary artery disease and evaluate angina.

**Description**

The MUGA scan is a series of images that demonstrate the flow of blood through the heart, providing information about heart muscle activity. Before images are taken, a radionuclide is injected into the bloodstream, a process that requires two injections in most health care facilities. The first injection contains a chemical that adheres to red blood cells, and the second contains a radioactive tracer (Tc99m) that attaches to that chemical. Alternatively, the two chemicals can be mixed together first and then injected, but the material tends to accumulate in bone and may obscure the heart.

The pictures are taken via gamma camera driven by a computer program that times the images, processes the information, and performs the mathematical calculations to provide ejection fraction and demonstrate wall motion. Images are obtained at various intervals during the cardiac cycle. Electrodes are placed on the patient so that a time frame can be established, for example, the time period between each "wave" (a part of the cardiac cycle seen on an EKG). The time frame is divided into several intervals, or "multiple gates." The result is a series of pictures showing the left and right ventricles at end-diastole (when the heart is dilated and filled with blood) and end-systole (when the heart is contracted and blood is being pumped out), and a number of stages in between.

A MUGA scan is performed in a hospital nuclear medicine department or in an outpatient facility. It takes approximately 30 minutes to one hour. The patient lies down on a bed alongside the gamma camera, receives the radionuclide injections, and multiple

## KEY TERMS

**Ejection fraction**—The fraction of blood in the ventricle that is ejected during each beat. One of the main advantages of the MUGA scan is its ability to measure ejection fraction, one of the most important measures of the heart's performance.

**Electrocardiogram**—Also known as an EKG, less often as an ECG. A test in which electrodes are placed on the body to record the heart's electrical activities.

**Ischemia**—A decreased supply of oxygenated blood to a body part or organ, often marked by pain and organ dysfunction, as in ischemic heart disease.

**Non-invasive**—A procedure that does not penetrate the body.

images are taken. If a stress study is indicated, the rest study is performed first. In a stress study, the patient usually lies on a special bed fitted with a bicycle apparatus. While an image is being recorded, the patient is asked to cycle for about two minutes, then the resistance of the wheels is increased. After two more minutes of **exercise**, another image is obtained and the resistance is increased again. Blood pressure and ECG are monitored during the procedure. After the stress portion is finished, one more resting, or recovery, study is obtained.

## Preparation

Standard preparation for an ECG is required. Special handling of nuclear materials by a nuclear medicine technologist may be required for the injections.

## Aftercare

The patient may resume normal activities immediately following the test.

## Normal results

A normal MUGA scan should not demonstrate areas of akinesis (lack of movement), or hypokinesis (decreased movement) of the heart muscle walls. Abnormal motion, especially in the left ventricle, is suggestive of an infarct or other myocardial defect. The ejection fraction is a measure of heart function, and should be within the normal limits established by the testing facility.

## Muscle relaxants

### Definition

Skeletal muscle relaxants are drugs that relax striated muscles (those that control the skeleton). They are a separate class of drugs from the muscle relaxant drugs used during intubations and surgery to reduce the need for anesthesia and facilitate intubation.

### Purpose

Skeletal muscle relaxants may be used for relief of spasticity in neuromuscular diseases such as multiple sclerosis, as well as for spinal cord injury and stroke. They may also be used for pain relief in minor strain injuries and control of the muscle symptoms of tetanus. Dantrolene (Dantrium) has been used to prevent or treat malignant hyperthermia in surgery.

## KEY TERMS

**Central nervous system (CNS)**—The brain and spinal cord.

**Intrathecal**—Introduced into or occurring in the space under the arachnoid membrane that covers the brain and spinal cord.

**Pregnancy category**—A system of classifying drugs according to their established risks for use during pregnancy: category A: controlled human studies have demonstrated no fetal risk; category B: animal studies indicate no fetal risk, and there are no adequate and well-controlled studies in pregnant women; category C: no adequate human or animal studies, or adverse fetal effects in animal studies, but no available human data; category D: evidence of fetal risk, but benefits outweigh risks; category X: evidence of fetal risk, which outweigh any benefits.

**Sedative**—Medicine used to treat nervousness or restlessness.

**Spasm**—Sudden, involuntary tensing of a muscle or a group of muscles.

**Tranquilizer (minor)**—A drug that has a calming effect and is used to treat anxiety and emotional tension.

## Description

The muscle relaxants are divided into two groups: centrally acting and peripherally acting. The centrally acting group appears to act on the central nervous system (CNS), and contains 10 drugs that are chemically different. Only dantrolene has a direct action at the level of the nerve-muscle connection.

Baclofen (Lioresal) may be administered orally or intrathecally (introduced into the space under the arachnoid membrane that covers the brain and spinal cord) for control of spasticity due to neuromuscular disease.

Several drugs, including carisoprodol (Soma), chlorphenesin (Maolate), chlorzoxazone (Paraflex), cyclobenzaprine (Flexeril), diazepam (Valium), metaxalone (Skelaxin), methocarbamol (Robaxin), and orphenadrine (Norflex), are used primarily as an adjunct for rest in management of acute muscle spasms associated with sprains. Muscle relaxation may also be an adjunct to physical therapy in rehabilitation following stroke, spinal cord injury, or other musculoskeletal conditions.

Diazepam and methocarbamol are also used by injection for relief of tetanus.

## Recommended dosage

Dose varies with the drug, route of administration, and purpose. There may be individual variations in absorption that require doses higher than those usually recommended (particularly with methocarbamol). The consumer is advised to consult specific references or ask a doctor for further information.

## Precautions

All drugs in the muscle relaxant class may cause sedation. Baclofen, when administered intrathecally, may cause severe CNS depression with cardiovascular collapse and respiratory failure.

Diazepam may be addictive, and is a controlled substance under federal law.

Dantrolene has a potential for hepatotoxicity. The incidence of symptomatic hepatitis is dose related, but may occur even with a short period of doses at or above 800 mg per day, which greatly increases the risk of serious liver injury. Overt hepatitis has been most frequently observed between the third and twelfth months of therapy. Risk of liver injury appears to be greater in women, in patients over 35 years of age, and in patients taking other medications in addition to dantrolene.

Tizanidine may cause low blood pressure, but this may be controlled by starting with a low dose and increasing it gradually. Rarely, the drug may cause liver damage.

Methocarbamol and chlorzoxazone may cause harmless color changes in urine—orange or reddish purple with chlorzoxazone; and purple, brown, or green with methocarbamol. The urine will return to its normal color when the patient stops taking the medicine.

Most drugs in the muscle relaxant class are well tolerated, but not all of these drugs have been evaluated for safety in pregnancy and breastfeeding.

Baclofen is pregnancy category C. It has caused fetal abnormalities in rats at doses 13 times above the human dose. Baclofen passes into breast milk, so breastfeeding while taking baclofen is not recommended.

Diazepam is category D. All benzodiazepines cross the placenta. Although the drugs appear to be safe for use during the first trimester of pregnancy, use later in pregnancy may be associated with cleft lip and palate. Diazepam should not be taken while breastfeeding. It was found that infants who were breastfed while their mothers took diazepam were excessively sleepy and lethargic.

Dantrolene is category C. In animal studies, it has reduced the rate of survival of the newborn when given in doses seven times the normal human dose. Mothers should not breastfeed while receiving dantrolene.

### Interactions

Skeletal muscle relaxants have many potential drug interactions. It is recommended that individual references be consulted.

Because these drugs cause sedation, they should be used with caution when taken with other drugs that may also cause drowsiness.

The activity of diazepam may be increased by drugs that inhibit its metabolism in the liver. These include cimetidine, oral contraceptives, disulfiram, fluoxetine, isoniazid, ketoconazole, metoprolol, propoxyphene, propranolol, and valproic acid.

Dantrolene may have an interaction with estrogens. Although no interaction has been demonstrated, the rate of liver damage in women over the age of 35 who were taking estrogens is higher than in other groups.

## Myelography

### Definition

Myelography is an x-ray examination of the spinal canal. A contrast agent is injected through a needle into the space around the spinal cord to display the spinal cord, spinal canal, and nerve roots on an x ray.

### Purpose

The purpose of a myelogram is to evaluate the spinal cord and nerve roots for suspected compression. Pressure on these delicate structures causes pain or other symptoms. A myelogram is performed when precise detail about the spinal cord is needed to make a definitive diagnosis. In most cases, myelography is used after other studies, such as **magnetic resonance imaging** (MRI) or a computed tomography scan (CT), have not provided enough information to be certain of the diagnosis. Sometimes myelography followed by CT scan is an alternative for patients who cannot have an MRI scan, because they have a pacemaker or other implanted metallic device.

A herniated or ruptured intervertebral disc, or related condition such as disc bulge or protrusion, popularly known as a slipped disc, is one of the most common causes for pressure on the spinal cord or nerve roots. The condition is popularly known as a pinched nerve. Discs are pads of fiber and cartilage that contain rubbery tissue. They lie between the vertebrae, or individual bones, which make up the spine.

Discs act as cushions, accommodating strains, shocks, and position changes. A disc may rupture suddenly, due to injury or a sudden strain with the spine in an unnatural position. In other cases, the problem may come on gradually as a result of progressive deterioration of the discs with aging. The lower back is the most common area for this problem, but it sometimes occurs in the neck, and rarely in the upper back. A myelogram can help accurately locate the disc or discs involved.

Myelography may be used when a tumor is suspected. Tumors can originate in the spinal cord or in tissues surrounding the cord. Cancers that have started in other parts of the body may spread or metastasize in the spine. It is important to precisely locate the mass causing pressure so effective treatment can be undertaken. Patients with known cancer who develop back pain may require a myelogram for evaluation.

Other conditions that may be diagnosed using myelography include arthritic bony growths (spurs), narrowing of the spinal canal (spinal stenosis), or malformations of the spine.

### Description

Myelograms can be performed in a hospital x-ray department or in an outpatient radiology facility. The patient lies face down on the x-ray table. The radiologist first looks at the spine under fluoroscopy, and the images appear on a monitor screen. This is done to

**Myelogram of the lumbar spine.** (ISM/Phototake. Reproduced by permission.)

find the best location to position the needle. The skin is cleaned, numbed with local anesthetic, and then the needle is inserted. Occasionally, a small amount of cerebrospinal fluid, the clear fluid that surrounds the spinal cord and brain, may be withdrawn through the needle and sent for laboratory studies. Contrast material (dye that shows up on x rays) is then injected.

The x-ray table is tilted slowly, allowing the contrast material to reach different levels in the spinal canal. The flow is observed under fluoroscopy, and x rays are taken with the table tilted at various angles. A footrest and shoulder straps or supports keep the patient from sliding.

In many instances, a CT scan of the spine is performed immediately after a myelogram, while the contrast material is still in the spinal canal. This helps outline internal structures more clearly.

A myelogram takes approximately 30–60 minutes. A CT scan adds about another hour to the examination. If the procedure is done as an outpatient exam, some facilities prefer the patient to stay in a recovery area up to four hours.

Patients who are unable to lie still or cooperate with positioning should not have this examination. Severe congenital spinal abnormalities may make the

## KEY TERMS

**Contrast agent**—Also called a contrast medium, this is usually a barium or iodine dye that is injected into the area under investigation. The dye makes the interior body parts more visible on an x-ray film. For myelograms, an iodine based contrast agent is used.

examination technically difficult to carry out. Patients with a history of severe allergic reaction to contrast material (x-ray dye) should report this to their physician prior to having myelography. Medications to minimize the risk of severe reaction may be recommended before the procedure. Given the invasive nature and risks of myelograms and increased anatomic detail provided by MRI or CT, myelograms are generally not used as the first imaging test.

### Preparation

Patients should be well-hydrated at the time they are undergoing a myelogram. Increasing fluids the day before the study is usually recommended. All food and fluid intake should be stopped approximately four hours before the procedure.

Certain medications may need to be stopped for one to two days before myelography is performed. These include some antipsychotics, antidepressants, blood thinners, and diabetic medications. Patients should discuss this with their physician or the staff at the facility where the study is to be done.

Patients who smoke may be asked to stop the day before the test. This helps decrease the chance of nausea or headaches after the myelogram. Immediately before the examination, patients should empty their bowels and bladder.

### Aftercare

After the examination is complete, the patient usually rests for several hours, with the head elevated. Extra fluids are encouraged, to help eliminate the contrast material and prevent headaches. A regular diet and routine medications may be resumed. Strenuous physical activities, especially those that involve bending over, may be discouraged for one or two days. The physician should be notified if the patient develops a fever, excessive nausea and vomiting, severe headache, or a stiff neck.

### Risks

Headache is a common complication of myelography. It may begin several hours to several days after the examination. The cause is thought to be changes in cerebrospinal fluid pressure, not a reaction to the dye. The headache may be mild and easily alleviated with rest and increased fluids. Sometimes, nonprescription medicines are recommended. In some instances, the headache may be more severe and require stronger medication or other measures for relief. Many factors influence whether the patient develops this problem, including the type of the needle used and his or her age and gender. Patients with a history of chronic or recurrent headaches are more likely to develop a headache after a myelogram.

The chance of a reaction to the contrast material is a very small, but potentially significant risk. It is estimated that only 5–10% of patients experience any effect from contrast exposure. The vast majority of reactions are mild, such as sneezing, nausea, or anxiety. These usually resolve by themselves. A moderate reaction, like wheezing or hives, may be treated with medication, but is not considered life threatening. Severe reactions, such as heart or respiratory failure, occur very infrequently, and require emergency medical treatment.

Rare complications of myelography include injury to the nerve roots from the needle or from bleeding into the spaces around the roots. Inflammation of the delicate covering of the spinal cord, called arachnoiditis, or infections, can also occur. Seizures are another very uncommon complication reported after myelography.

### Normal results

A normal myelogram shows nerves that appear normal, and a spinal canal of normal width, with no areas of constriction or obstruction.

A myelogram may also reveal a herniated disk, tumor, bone spurs, or narrowing of the spinal canal (spinal stenosis).

## Myocardial resection

### Definition

Myocardial resection is a surgical procedure in which a portion of the heart muscle is removed.

### Purpose

Myocardial resection is done to improve the stability of the heart function or rhythm. Also known as endocardial resection, this open-heart surgery is done to destroy or remove damaged areas. These areas can generate life-threatening heart rhythms. Conditions resulting in abnormal heart rhythms caused by re-entry pathways or aberrant cells are corrected with this treatment.

Areas of the heart involved in a myocardial infarction change in contractility and function, becoming scar tissue that thins and hinders its ability to contract. Removing this diseased area can improve myocardial contractility reversing the severity of chronic heart failure. This procedure has shown promise for patients with chronic heart failure, in order to improve cardiac output and quality of life.

### Demographics

Patients are not limited by age, race or sex when being evaluated for myocardial resection surgery. Patients who experience angina, congestive heart failure, arrhythmias, and pulmonary edema (fluid on the lungs) are candidates for this procedure. Contraindications—conditions in which the surgery is not recommended—include right heart failure, high pressure in the blood coming from left ventricle (lower chamber), and pulmonary hypertension (high blood pressure in the circulation around the lungs).

### Description

After receiving a general anesthetic, an incision will be made in the chest to expose the heart. Cardiopulmonary bypass (to a heart-lung machine) will be instituted since this procedure requires direct visualization of the heart muscle. Since this is a true open

## KEY TERMS

**Arrhythmia**—An abnormal heart rhythm. Examples are a slow, fast, or irregular heart rate.

**Cardiac catheterization**—A diagnostic procedure in which a thin tube is inserted into an artery or vein and guided to the heart using x rays. The function of the heart and blood vessels can be evaluated using this technique.

**Dacron graft**—A synthetic material used in the repair or replacement of blood vessels.

**Ejection fraction**—The amount of blood pumped out at each heartbeat, usually referred to as a percentage.

**Implantable cardioverter-defibrillator**—A device placed in the body to deliver an electrical shock to the heart in response to a serious abnormal rhythm.

**Infarction**—Tissue death resulting from a lack of oxygen to the area.

**Intra-aortic balloon pump**—A temporary device inserted into the femoral artery and guided up to the aorta. The small balloon helps strengthen heart contractions by maintaining improved blood pressure.

**Radiofrequency ablation**—A procedure in which a catheter is guided to an area of heart where abnormal heart rhythms originate. The cells in that area are killed using a mild radiofrequency energy to restore normal heart contractions.

**Wolff-Parkinson-White syndrome**—An abnormal, rapid heart rhythm, due to an extra pathway for the electrical impulses to travel from the atria to the ventricles.

heart procedure, the heart will be unable to pump blood during the surgery.

### *Arrhythmias*

When the exact source of the abnormal rhythm is identified, it is removed. If there are areas around the source that may contribute to the problem, they can be frozen with a special probe. The amount of tissue removed is so small, usually only 2–3 mm, that there is no damage to the structure of the heart.

### *Ventricular reconstruction*

Weakened myocardium (heart muscle) allows the heart to remodel and become less efficient at pumping blood. The goal is to remove the damaged region of the free wall of the left ventricle along with any

involved septum. The heart is then reconstructed to provide a more elliptical structure that pumps blood more efficiently. In some instances a Dacron graft is used to replace the removed myocardium to aid in the reconstruction.

### Diagnosis/Preparation

Diagnosis of arrhythmias begins with a Holter monitor that can identify the type of arrhythmia. This is followed by a **cardiac catheterization** to find the aberrant cells generating the arrhythmia. The patient is then recommended for open-heart surgery to remove the cells generating the arrhythmia.

Diagnosis of chronic heart failure is demonstrated by a cardiac catheterization or nuclear medicine study. During cardiac catheterization, the patient's cardiac function will be measured by cardiac output, ejection fraction and cardiovascular pressures. A nuclear medicine study can demonstrate areas of myocardium that are damaged. Muscle that is akinetic (does not move) will be identified. This information allows the surgeon to identify candidates for myocardial resection.

This is major surgery and should be the treatment of choice only after medications have failed and the use of an **implantable cardioverter-defibrillator** (a device that delivers electrical shock to control heart rhythm) has been ruled out along with medical therapy.

Prior to surgery, the physician will explain the procedure and order blood tests of the formed blood elements and electrolytes.

### Aftercare

Immediately after surgery, the patient will be transferred to the **intensive care unit** for further cardiac monitoring. Any medications to improve cardiac performance will be weaned as necessary to allow the native heart function to return. The patient will be able to leave the hospital within five days, assuming there are no complications. Complications may include the need for intra-aortic balloon pump **ventricular assist device**, surgical bleeding, and infection.

### Risks

The risks of myocardial resection are based in large part on the patient's underlying heart condition and, therefore, vary greatly. The procedure involves opening the heart, so the person is at risk for the complications associated with major heart surgery, such as stroke, shock, infection, and hemorrhage. Since the amount

## WHO PERFORMS THIS PROCEDURE AND WHERE IS IT PERFORMED?

Electrophysiologists, cardiac surgeons and cardiologists, specially trained in cardiac electrical signaling and ventricular reconstruction have undergone specific training in these procedures. The number of patients suitable for these procedures are limited so experienced physicians should be sought to provide medical treatment.

of myocardium to remove is not precise, a patient may demonstrate little benefit in cardiac performance. If not enough or too much tissue is removed, the patient will continue to have heart problems.

General anesthetic with inhalation gases should be avoided as they can promote arrhythmias. Therefore, anesthesia should be limited to intravenous medications.

### Normal results

Postoperative treatment for arrhythmias demonstrates 90% of patients are arrhythmia-free at the end of one year. A study of 245 patients published in 2001, demonstrated a 98% event free survival rate for patients after one year. After five years, 80% of patients had remained event free.

### Morbidity and mortality rates

Cardiopulmonary bypass has an associated risk of complications separate from myocardial resection, with age greater than 70 years of age being a predictor for increased morbidity and mortality. In 1999, over 350,000 total procedures were performed using cardiopulmonary bypass.

In the study of 245 patients, ventricular reconstruction by myocardial resection was found to have an associated in-hospital mortality rate of 78.1%.

### Alternatives

If myocardial resection is being performed to prevent arrhythmia generation, new techniques allow for minimally invasive procedures to be performed, including radiofrequency ablation performed in an electrophysiology laboratory with mild sedation, instead of general anesthetic.

If ventricular restoration is contraindicated, medical treatment will be continued. Mechanical

## QUESTIONS TO ASK THE DOCTOR

- In the past year, how many of these procedures have been performed by the physician?
- What is the standard of care for a patient with arrhythmias/congestive heart failure/angina/pulmonary edema?
- What alternative therapies can be suggested, and what is the difference in survival outcomes at one and five years?
- Where can additional information be found about this procedure?
- What new technologies are available to assist in completing the procedure successfully?
- What are the risks associated with cardiopulmonary bypass?
- What type of post-operative course can be expected?
- How long will it be before normal activities can be reinstituted, such as driving, exercise and returning to work?

circulatory assist with a ventricular assist device may be a suitable option. Heart transplant and total artificial heart should also be explored as alternative therapies.

## Myomectomy

### Definition

Myomectomy is the removal of fibroids (non-cancerous tumors) from the wall of the uterus. Myomectomy is the preferred treatment for symptomatic fibroids in women who want to keep their uterus. Larger fibroids must be removed with an abdominal incision, but small fibroids can be taken out by **laparoscopy** or **hysteroscopy**.

### Purpose

A myomectomy can remove uterine fibroids that are causing symptoms such as abnormal bleeding or pain. It is an alternative to surgical removal of the whole uterus (**hysterectomy**). The procedure can relieve fibroid-induced menstrual symptoms that have not responded to medication. Myomectomy also may be an effective treatment for infertility caused by the presence of fibroids.

### Demographics

Uterine fibroids are more common among African-American women than among women of other ethnicities. Fibroids affect 20–40% of all women over the age of 35, and 50% of African-American women. A 2001 study by the National Institute of Environmental Health Sciences found that the incidence of fibroids among African-American women in their late 40s was as high as 80%, while approximately 70% of white women of that age were diagnosed as having fibroids. Women who are obese, are older, or started menstruating at an early age are also at an increased risk of developing uterine fibroids. Another study published in 2003 indicated that women with less education were more likely to have a hysterectomy performed to treat fibroids, instead of a less-invasive procedure such as myomectomy.

### Description

Usually, fibroids are buried in the outer wall of the uterus, and abdominal surgery is required. If they are on the inner wall of the uterus, uterine fibroids can be removed using hysteroscopy. If they are on a stalk (pedunculated) on the outer surface of the uterus, laparoscopy can be performed.

Removing fibroids through abdominal surgery is a more difficult and slightly more risky operation than a hysterectomy. This is because the uterus bleeds from the sites where the fibroids were removed, and it may be difficult or impossible to stop the bleeding. This

Uterine fibroids can occur within the uterine cavity, in the mucous layer, or in the muscle (A). To remove them by myomectomy, an incision is made into the woman's lower abdomen (B). An incision is made in the uterus over the tumor (C), and it is removed (D). (Illustration by GGS Information Services. Cengage Learning, Gale.)

surgery is usually performed under **general anesthesia**, although some patients may be given a spinal or epidural anesthesia.

The incision may be horizontal (the "bikini" incision) or a vertical incision from the navel downward. After separating the muscle layers underneath the skin, the surgeon makes an opening in the abdominal wall. Next, the surgeon makes an incision over each fibroid, grasping and pulling out each growth.

Every opening in the uterine wall is then stitched with sutures. The uterus must be meticulously repaired in order to eliminate potential sites of bleeding or

infection. The surgeon then sutures the abdominal wall and muscle layers above it with absorbable **stitches**, and closes the skin with clips or non-absorbable stitches.

When appropriate, a laparoscopic myomectomy may be performed. In this procedure, the surgeon removes fibroids with the help of a viewing tube (laparoscope) inserted into the pelvic cavity through an incision in the navel. The fibroids are removed through a tiny incision under the navel that is much smaller than the 4–5 in (10–13 cm) opening required for a standard myomectomy.

## KEY TERMS

**Adhesions**—Bands of scar tissue between organs that can form after surgery or trauma.

**Cesarean section**—A surgical procedure in which incisions are made through a woman's abdomen and uterus to deliver her baby.

**Epidural anesthesia**—A method of pain relief for surgery in which local anesthetic is injected into the epidural space in the middle and lower back.

If the fibroids are small and located on the inner surface of the uterus, they can be removed with a thin, telescope-like device called a hysteroscope. The hysteroscope is inserted into the vagina through the cervix and into the uterus. This procedure does not require any abdominal incision, so hospitalization is shorter.

## Diagnosis/Preparation

Surgeons often recommend hormone treatment with a drug called leuprolide (Lupron) two to six months before surgery in order to shrink the fibroids. This makes the fibroids easier to remove. In addition, Lupron stops menstruation, so women who are anemic have an opportunity to build up their blood count. While the drug treatment may reduce the risk of excess blood loss during surgery, there is a small risk that smaller fibroids might be missed during myomectomy, only to enlarge later after the surgery is completed.

## Aftercare

Patients may need four to six weeks of recovery following a standard myomectomy before they can return to normal activities. Women who have had laparoscopic or hysteroscopic myomectomies, however, can usually recover completely within one to three weeks.

## Risks

The risks of a myomectomy performed by a skilled surgeon are about the same as hysterectomy (one of the most common and safest surgeries). Removing multiple fibroids is more difficult and slightly more risky. Possible complications include:

- infection
- blood loss
- weakening of the uterine wall to the degree that future deliveries need to be performed via cesarean section

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

Myomectomies are usually performed in a hospital operating room or an outpatient setting by a gynecologist, a medical doctor who has specialized in the areas of women's general health, pregnancy, labor and childbirth, prenatal testing, and genetics.

- adverse reactions to anesthesia
- internal scarring (and possible infertility)
- reappearance of new fibroids

There is a risk that removal of the fibroids may lead to such severe bleeding that the uterus itself will have to be removed. Because of the risk of blood loss during a myomectomy, patients may want to consider banking their own blood before surgery (**autologous blood donation**).

## Normal results

Removal of uterine fibroids will usually improve any side effects that the patient may have been suffering from, including abnormal bleeding and pain. Under normal circumstances, a woman who has had a myomectomy will be able to become pregnant, although she may have to deliver via **cesarean section** if the uterine wall has been weakened.

## Morbidity and mortality rates

Depending on the surgical approach, the rate of complications for myomectomy is about the same as those for hysterectomy (anywhere between 3% and 9%). The rate of fibroid reoccurrence is approximately 15%. Adhesions (bands of scar tissue between organs that can form after surgery or trauma) occur in 15–53% of women postoperatively.

## Alternatives

Hysterectomy (partial or full removal of the uterus) is a common alternative to myomectomy. The most frequent reason for hysterectomy in the United States is to remove fibroid tumors, accounting for 30% of all hysterectomies. A subtotal (or partial) hysterectomy is the preferable procedure because it removes the least amount of tissue (i.e., the opening to the cervix is left in place).

## QUESTIONS TO ASK THE DOCTOR

- Why is a myomectomy being recommended?
- How many myomectomies do you perform a year?
- What type of myomectomy will be performed?
- What are the risks if I decide against the myomectomy?
- What alternatives to myomectomy are available to me?

Fibroid embolization is a relatively new, less-invasive procedure in which blood vessels that feed the fibroids are blocked, causing the growths to shrink. The blood vessels are accessed via a catheter inserted into the femoral artery (in the upper thigh) and injected with tiny particles that block the flow of blood. The fibroids subsequently decrease in size and the patient's symptoms improve.

## Myringotomy and ear tubes

### Definition

Myringotomy is a surgical procedure in which a small incision is made in the eardrum (the tympanic membrane), usually in both ears. The English word is derived from *myringa*, modern Latin for drum membrane, and *tomē*, Greek for cutting. It is also called myringocentesis, tympanotomy, tympanostomy, or **paracentesis** of the tympanic membrane. Fluid in the middle ear can be drawn out through the incision.

Ear tubes, or tympanostomy tubes, are small tubes open at both ends that are inserted into the incisions in the eardrums during myringotomy. They come in various shapes and sizes and are made of plastic, metal, or both. They are left in place until they fall out by themselves or until they are removed by a doctor.

### Purpose

Myringotomy with the insertion of ear tubes is an optional treatment for inflammation of the middle ear with fluid collection (effusion) that lasts longer than three months (chronic otitis media with effusion) and does not respond to drug treatment. This condition is also called **glue ear**. Myringotomy is the recommended treatment if the condition lasts four to six months. Effusion refers to the collection of fluid that escapes from blood vessels or the lymphatic system. In this case, the effusion collects in the middle ear.

Initially, acute inflammation of the middle ear with effusion is treated with one or two courses of **antibiotics**. Antihistamines and decongestants have been used, but they have not been proven effective unless there is also hay fever or some other allergic inflammation that contributes to the problem. Myringotomy with or without the insertion of ear tubes is *not* recommended for initial treatment of otherwise healthy children with middle ear inflammation with effusion.

## Myringotomy and ear tubes

During a myringotomy, an incision is made into the ear drum, or tympanic membrane (B). The fluid in the ear canal is suctioned out (C), and a small tube is put in place to allow future drainage in the event of an infection (D). (Illustration by GGS Information Services. Cengage Learning, Gale.)

## KEY TERMS

**Acute otitis media**—Inflammation of the middle ear with signs of infection lasting less than three months.

**Adenoids**—Clusters of lymphoid tissue located in the upper throat above the roof of the mouth. Some doctors think that removal of the adenoids may lower the rate of recurrent otitis media in high-risk children.

**Barotrauma**—Ear pain caused by unequal air pressure on the inside and outside of the ear drum. Barotrauma, which is also called pressure-related ear pain or barotitis media, is the most common reason for myringotomies in adults.

**Chronic otitis media**—Inflammation of the middle ear with signs of infection lasting three months or longer.

**Effusion**—The escape of fluid from blood vessels or the lymphatic system and its collection in a cavity, in this case, the middle ear.

**Eustachian tube**—A canal that extends from the middle ear to the pharynx.

**Insufflation**—Blowing air into the ear as a test for the presence of fluid in the middle ear.

**Middle ear**—The cavity or space between the eardrum and the inner ear. It includes the eardrum, the three little bones (hammer, anvil, and stirrup) that transmit sound to the inner ear, and the Eustachian tube, which connects the inner ear to the nasopharynx (the back of the nose).

**Otolaryngologist**—A surgeon who specializes in treating disorders of the ears, nose, and throat.

**Tympanic membrane**—The eardrum. A thin disc of tissue that separates the outer ear from the middle ear.

**Tympanostomy tube**—Ear tube. A small tube made of metal or plastic that is inserted during myringotomy to ventilate the middle ear.

In about 10% of children, the effusion lasts for three months or longer, when the disease is considered chronic. In children with chronic disease, systemic steroids may help, but the evidence is not clear, and there are risks.

When medical treatment doesn't stop the effusion after three months in a child who is one to three years old, is otherwise healthy, and has hearing loss in

both ears, myringotomy with insertion of ear tubes becomes an option. If the effusion lasts for four to six months, myringotomy with insertion of ear tubes is recommended.

The purpose of myringotomy is to relieve symptoms, to restore hearing, to take a sample of the fluid to examine in the laboratory in order to identify any microorganisms present, or to insert ear tubes.

Ear tubes can be inserted into the incision during myringotomy and left there. The eardrum heals around them, securing them in place. They usually fall out on their own in six to 12 months or are removed by a doctor.

While the tubes are in place, they keep the incision from closing, keeping a channel open between the middle ear and the outer ear. This allows fresh air to reach the middle ear, allowing fluid to drain out, and preventing pressure from building up in the middle ear. The patient's hearing returns to normal immediately and the risk of recurrence diminishes.

## Demographics

In the United States, myringotomy and tube placement have become a mainstay of treatment for recurrent otitis media in children. More than 500,000 procedures are performed annually, making myringotomy the most common pediatric, ambulatory operation performed in the U.S.

Myringotomy in adults is a less common procedure than in children, primarily because adults benefit from certain changes in the anatomy of the middle ear that occur after childhood. In particular, the adult ear is less likely to accumulate fluid because the Eustachian tube, which connects the middle ear to the throat area, lies at about a 45-degree angle from the horizontal. This relatively steep angle means that the force of gravity helps to keep fluids from the throat containing disease organisms out of the middle ear. In children, however, the Eustachian tube is only about 10 degrees above the horizontal, which makes it relatively easy for disease organisms to migrate from the nose and throat into the inner ear. Myringotomies in adults are usually performed as a result of barotrauma, which is also known as pressure-related ear pain or barotitis media. Barotrauma refers to earache caused by unequal air pressure on the inside and outside of the eardrum. Adults with very narrow Eustachian tubes may experience barotrauma in relation to scuba diving, using elevators, or frequent flying. A myringotomy with tube insertion may be performed if the condition is not helped by decongestants or antibiotics.

Most myringotomies in children are performed in children between one to two years of age. One Canadian study found that the number of myringotomies performed was 12.8 per thousand for children 11 months old or younger; 54.2 per thousand for children between 12 and 23 months old; and 11.1 per thousand for children between three and 15 years old. Sex and race do not appear to affect the number of myringotomies in any age group, although boys are reported to have a slightly higher rate of ear infections than girls.

## Description

When a conventional myringotomy is performed, the ear is washed, a small incision made in the eardrum, the fluid sucked out, a tube inserted, and the ear packed with cotton to control bleeding.

Recent developments include the use of medical acupuncture to control pain during the procedure, and the use of carbon dioxide lasers to perform the myringotomy itself. Laser-assisted myringotomy can be performed in a doctor's office with only a local anesthetic. It has several advantages over the older technique: it is less painful; less frightening to children; and minimizes the need for tube insertion because the hole in the eardrum produced by the laser remains open longer than an incision done with a scalpel.

Another technique to keep the incision in the eardrum open without the need for tube insertion is application of a medication called mitomycin C, which was originally developed to treat bladder cancer. The mitomycin prevents the incision from sealing over. As of 2007, however, this approach is still being studied.

There has also been an effort to design ear tubes that are easier to insert or to remove, and to design tubes that stay in place longer. As of 2003, ear tubes come in various shapes and sizes.

## Diagnosis/Preparation

The diagnosis of otitis media is based on the doctor's visual examination of the patient's ear and the patient's symptoms. Patients with otitis media complain of earache and usually have a fever, sometimes as high as 105°F (40.5°C). There may or may not be loss of hearing. Small children may have nausea and vomiting. When the doctor looks in the ear with an otoscope, the patient's eardrum will look swollen and may bulge outward. The doctor can evaluate the presence of fluid in the middle ear either by blowing air into the ear, known as insufflation, or by tympanometry, which is an indirect measurement of the mobility of the eardrum. If the eardrum has already ruptured,

there may be a watery, bloody, or pus-streaked discharge.

Fluid removed from the ear can be taken to a laboratory for culture. The most common bacteria that cause otitis media are *Pneumococcus*, *Haemophilus influenzae*, and *Moraxella catarrhalis*. Some cases are caused by viruses, particularly respiratory syncytial virus (RSV).

A child scheduled for a myringotomy should not have food or water for four to six hours before anesthesia. Antibiotics are usually not needed.

If **local anesthesia** is used, a cream containing lidocaine and prilocaine is applied to the ear canal about 30 minutes before the myringotomy. If medical acupuncture is used for pain control, the acupuncture begins about 40 minutes before surgery and is continued during the procedure.

## Aftercare

The use of antimicrobial drops is controversial. Water should be kept out of the ear canal until the eardrum is intact. A doctor should be notified if the tubes fall out.

## Risks

The risks include:

- cutting the outer ear
- formation at the myringotomy site of granular nodes due to inflammation
- formation of a mass of skin cells and cholesterol in the middle ear that can grow and damage surrounding bone (cholesteatoma)
- permanent perforation of the eardrum

It is also possible that the incision won't heal properly, leaving a permanent hole in the eardrum. This result can cause some hearing loss and increases the risk of infection.

The ear tube may move inward and get trapped in the middle ear, rather than move out into the external ear, where it either falls out on its own or can be retrieved by a doctor. The exact incidence of tubes moving inward is not known, but it could increase the risk of further episodes of middle-ear inflammation, inflammation of the eardrum or the part of the skull directly behind the ear, formation of a mass in the middle ear, or infection due to the presence of a foreign body.

The surgery may not be a permanent cure. As many as 30% of children undergoing myringotomy

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

Myringotomies are performed by family practitioners, pediatricians, and otolaryngologists, who are surgeons who specialize in treating disorders of the ears, nose, and throat.

A conventional myringotomy is usually done in an ambulatory surgical unit under general anesthesia, although some physicians do it in the office with sedation and local anesthesia, especially in older children and adults. In either case, it is considered same-day surgery. Laser-assisted myringotomies are usually performed in doctors' offices or outpatient surgery clinics.

with insertion of ear tubes need to undergo another procedure within five years.

The other risks include those associated with sedatives or **general anesthesia**. Some patients may prefer acupuncture for pain control in order to minimize these risks.

An additional element of **postoperative care** is the recommendation of many doctors that the child use ear plugs to keep water out of the ear during bathing or swimming to reduce the risk of infection and discharge.

### Normal results

Parents often report that children talk better, hear better, are less irritable, sleep better, and behave better after myringotomy with the insertion of ear tubes. Normal results in adults include relief of ear pain and ability to resume flying or deep-sea diving without barotrauma.

### Morbidity and mortality rates

Morbidity following myringotomy usually takes the form of either otorrhea, which is a persistent discharge from the ear, or changes in the size or texture of the eardrum. The risk of otorrhea is about 13%. If the procedure is repeated, the eardrum may shrink, retract, or become flaccid. The eardrum may also develop an area of hardened tissue. This condition is known as tympanosclerosis. The risk of hardening is 51%; its effects on hearing aren't known, but they appear to be insignificant.

## QUESTIONS TO ASK THE DOCTOR

- What alternatives to myringotomy might work for my child?
- How can I lower my child's risk of recurrent ear infections?
- Do you perform laser-assisted myringotomies?
- What is your opinion of removing my child's adenoids to lower the risk of future hospitalizations?

A report published in 2002 indicates that morbidity following myringotomy in the United States is highest among children from families of low socioeconomic status. The study found that children from poor urban families had more episodes of otorrhea following tube insertion than children from suburban families. In addition, the episodes of otorrhea in the urban children lasted longer.

Mortality rates are extremely low; case studies of fatalities following myringotomy are rare in the medical literature, and most involve adults.

### Alternatives

#### *Preventive measures*

There are several lifestyle issues related to high rates of middle ear infection. One of the most serious is parental smoking. One study of the effects of passive smoking on children's health estimated that as many as 165,000 of the myringotomies performed each year on American children are related to the use of tobacco in the household.

Studies have shown that children in daycare have a higher risk of chronic ear infection, and therefore a higher risk of needing myringotomy..

A third factor that affects a child's risk of recurrent middle ear infection is breastfeeding. Toddlers who were breastfed as infants for at least four months have a lower risk of ear infection than those who were bottlefed.

#### *Other surgical approaches*

Because the adenoids may harbor infection, when myringotomy and tube placement fails, **adenoidectomy** may be performed in order to resolve chronic otitis media.

*Alternative medicine*

According to Dr. Kenneth Pelletier, former director of the program in complementary and alternative medicine at Stanford University, there is some evidence that homeopathic treatment is effective in reducing the pain of otitis media in children and lowering the risk of recurrence.

## Necessary surgery

### Definition

Necessary surgery is a term that refers both to a medical requirement for the surgery determined by a physician and to an insurance plan's inclusion of the surgery in the covered conditions. For the most part, these two ways of talking about required surgery coincide. When they do not, the physician is asked to demonstrate to the insurance plan that the surgery is necessary by reference to the medical condition to be treated and the customary medical practice that deems it required as opposed to optional or elective.

### Purpose

Not all surgery is an emergency. Not all surgery is medically required. Some surgeries are for cosmetic or for aesthetic enhancements and are deemed optional or elective, both by physicians and by insurance plans.

Necessary surgery refers to surgical procedures that pertain to a condition that cannot be treated by other methods and, if left untreated, would threaten the life of the patient, fail to repair or improve a body function, increase the patient's pain, or prevent the diagnosis of a serious or painful condition. The emphasis here is that, according to medical judgment, surgery is mandated.

Not all necessary surgery is absolutely required until the patient is satisfied that he or she has all the information needed to opt for surgery. All surgery has risks and the decision to have surgery is one that needs to be made by both the physician and the patient.

### Description

The decision to have surgery should be made by the patient after:

- complete evaluation by a physician to determine if the surgery is medically indicated
- discussion with the physician about alternative treatments
- discussion that allows the patient to understand why the surgery is necessary, what the surgery involves, and why the particular procedure has been chosen by the surgeon
- discussion of the complete risks and benefits of the procedure
- second opinion has been enlisted about the surgery and its components and/or alternatives (Many health insurance plans require this step and will pay for the second opinion.)

Only after a physician has taken the condition and symptoms into account with a complete evaluation of alternatives, will surgery be judged to be necessary. During the course of this evaluation, and after non-surgical treatments have failed, the patient needs to be actively involved in understanding the actual procedure that might mitigate the condition, the full array of risks and benefits of the surgery, and why the surgeon has arrived at the particular procedure. The patient should understand the likelihood of danger or risk if he or she foregoes the surgery and the patient needs to understand that there may be a possibility of improvement, given sufficient time, without the surgery. Before choosing to undergo a particular surgical procedure, the patient should get a **second opinion** about the wisdom, efficacy, risk, and benefits of the procedure.

### Diagnosis/Preparation

Preparation for surgery should include knowing:

## KEY TERMS

**Alternatives to surgery**—Other treatments for the condition or illness that do not involve surgery; these are usually tried before surgery is an option.

**Elective surgery**—Surgery chosen by someone over 18 and/or a guardian for a patient that is not medically required for an illness, condition, or pain relief.

**Surgical alternatives**—Surgical options within a range of surgical procedures used to treat a specific condition.

- Where surgery will take place and the length of stay in the hospital. Some insurance companies may press for shorter hospital stays.
- What pain medication will be used, and how medications for home use will be ordered for discharge. The physician should know all medications that are currently being taken.
- Who will make decisions on the patient's behalf and with what legal authority, should the patient be unable to make a decision in the hospital. The physician and the nursing team need to know who this "patient advocate" is.
- What the visiting hours, rules, and limits on children are.
- That the hospital plans to accommodate any dietary restrictions the patient may have.
- That there is sufficient at-home assistance and resources for the patient upon discharge.
- The dietary and behavioral requirements for the days just preceding surgery.

## Needle bladder neck suspension

### Definition

Needle bladder neck suspension, also known as needle suspension, or paravaginal surgery, is performed to support the hypermobile, or moveable urethra using sutures to attach it to tissues covering the pelvic floor. Of the three popular surgical procedures for urethral instability and its results in urinary stress incontinence, needle bladder neck suspension is the quickest and easiest to perform. It has many variants, such as the Raz, Stamey, modified Pereyra, or Gattes procedures, but its long-term results are less impressive than other, more extensive, anti-incontinent surgeries.

### Purpose

Fifty years of work to treat incontinence, especially in women, has resulted in three types of surgery tied to essentially three causes of a particular type of incontinence related to muscle weakening of the urethra and the "gate-keeping" sphincter muscles. Stress urinary incontinence, the uncontrollable leakage of urine when pressure is put on the bladder during sneezing, coughing, laughing, or exercising, is very common in women. It is estimated to affect 50% of elderly women in long-term care facilities. The inability to hold urine has two causes. One has to do with support for the urethra and bladder, known as genuine stress incontinence (GSI), and the other is related to the inability of sphincter muscles, or intrinsic sphincter deficiency (ISD), to keep the opening of the bladder closed.

In GSI, weak muscles supporting the urethra allow it to be displaced and/or descend into the pelvic-floor fascia (connective tissues) and create cystoceles, or pockets. The goal of surgery for GSI is to stabilize the suburethral fascia to prevent the urethra from being overly mobile during increased abdominal pressure.

The other major source of stress incontinence is due to weakening of the internal muscles of the sphincter, as they affect closure of the bladder. These muscles, called the intrinsic sphincter muscles, regulate the opening and

## KEY TERMS

**Genuine stress incontinence (GSI)**—A specific term for a type of incontinence that has to do with the instability of the urethra due to weakened support muscles.

**Hypermobile urethra**—A term that denotes the movement of the urethra that allows for leakage or spillage of urine.

**Intrinsic sphincter deficiency**—A type of incontinence caused by the inability of the sphincter muscles to keep the bladder closed.

**Urinary stress incontinence**—The involuntary release of urine due to pressure on the abdominal muscles during exercise or laughing or coughing.

closing of the bladder when a decision is made to urinate. Deficiency of the intrinsic sphincter muscles causes the opening to remain open and thus leads to chronic incontinence. ISD is a source of severe stress incontinence and may be combined with urethral hypermobility.

The challenge of surgery for stress incontinence is to adequately evaluate the actual source of incontinence, whether GSI or ISD, and also to determine the likelihood of cystoceles that may need repair. Under good diagnostic conditions, surgery for stress incontinence will utilize a suprapubic (above the pubic area) procedure, or Burch procedure, to secure the hypermobile urethra and stabilize it in a neutral position. Surgery for ISD uses what is known as a **sling procedure**, or “hammock” effect, that uses auxiliary tissue to undergird the urethra and provide contractive pressure to the sphincter. Most stress incontinence surgeries fall into one of these two procedures and their variants.

Needle neck bladder suspension, the third most utilized procedure for stress incontinence, simply attempts to attach the urethra neck to the posterior pelvic wall through the vagina or abdomen in order to stabilize the urethra. It is, however, considered a poor choice in comparison to the other two procedures because of its lack of long-term efficacy and its high incidence of urinary retention as an operative complication.

## Demographics

More than 13 million people in the United States, both males and females, have urinary incontinence. Women experience it twice as often as men due to pregnancy, childbirth, menopause, and the structure of the female urinary and gynecological systems. Anyone can become incontinent due to neurological injury, birth

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

Surgery is performed by a urological surgeon who has a medical degree with advanced training in urology and in surgery. Surgery is performed in a general hospital.

defects, cardiac conditions, multiple sclerosis, and chronic conditions in later life. Incontinence does not naturally accompany old age but is associated with many chronic conditions that occur as age increases. Incontinence is highly associated with obesity and lack of **exercise**. As many as 15–30% of adults over 60 have some form of urinary incontinence. Stress incontinence is, by far, the most frequent form of incontinence and is the most common type of bladder control problem in younger and middle-age women.

## Description

Needle bladder neck suspension surgery can be performed as open abdominal or vaginal surgery, or laproscopically, which allows for small incisions, video magnification of the operative field, and precise placement of sutures. Under a general anesthetic, the patient is placed in a position on her back with legs in stirrups allowing access to the suprapubic area. A Foley catheter is inserted into the bladder. The open procedure involves the passage of a needle from the suprapubic area to the vagina with multiple sutures through looping. Cytoscopic monitoring (using an endoscope passed into the urethra) prevents passage of the needle through the bladder or the urethra. The laparoscopic method allows visualization of the needle pass made from the suprapubic area to the vagina and the looping technique. The vagina and the surrounding areas are thoroughly irrigated with an antibiotic solution throughout the procedure. The patient is discharged the same evening or the next morning with the catheter in place. She is kept on **antibiotics** and examined on the fourth day after surgery with the removal of the catheter. The follow-up examination includes wound inspection and a evaluation of residual urine. A pelvic examination is performed to check for bleeding or injury.

## Diagnosis/Preparation

Stress urinary incontinence can have a number of causes. It is important that patients confer with their physicians to rule out medication-related, psychological, and/or behavioral sources of incontinence as well as physical and neurological causes. This involves complete medical history, as well as medication, clinical,

## QUESTIONS TO ASK THE DOCTOR

- Is surgery my only alternative to living with urinary incontinence?
- Are there other surgical procedures that are more effective for my incontinence?
- Can you recommend any literature I can read that explains my surgical options for incontinence?
- Can you explain why this procedure is preferable to what is known as a “sling procedure?”

neurological, and radiographic evaluations. Once these are completed, urodynamic tests that evaluate the urethra, bladder, flow, urine retention, and leakage, are performed and allow the physician to determine the primary source of the stress incontinence. Patients who are obese and/or engage in high-impact exercise are not good candidates for this surgery. Patients with ISD may not be cured with this procedure, since it is primarily intended to treat the hypermobile urethra.

### Morbidity and mortality rates

**Urologic surgery** has inherent morbidity and mortality risks related primarily to **general surgery**, with lung conditions, blood clots, infections, and cardiac events occurring in a small percentage of surgeries, independent of the type of procedure. In addition, the American Urological Association (AUA) has concluded that needle suspension surgery has a number of complications related directly to suturing in the suprapubic area. These complications include:

- a 5% incidence of bladder injury
- urethral injury, although rare, in a small percentage of cases
- bleeding, with an incidence of 3–5%, primarily from the area below the pubic area
- nerve entrapment (8–16% of cases) due to lateral placement of the sutures into the fascia at the back of the suprapubic area (This has improved with a change in the placement of sutures.)
- wound infections in about 7% of cases, with higher rates among those with diabetes or obesity

These operative complications, coupled with the procedure's high rate (10%) of reported pain after surgery, and its relatively high rate (5%) of urinary retention lasting longer than four weeks, have resulted in needle neck suspension having a limited role in the management of stress urinary incontinence.

### Normal results

Despite modifications in the needle suspension procedure, the long-term outcome of the procedure does not indicate its lasting efficacy. According to a recent report by the AUA, a study of the effects of needle suspension found only a 72-91% cure, or “dry rate,” after 48 months, with delayed failures of sutures in a very high percentage (33-80%) of cases.

## Negative pressure rooms

### Definition

A negative pressure room is a volumetric space in which the internal atmospheric pressure is lower than the spaces into which it opens.

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

An infectious disease or emergency physician usually admits patients to negative pressure rooms in hospitals or other healthcare facilities.

### Purpose

The purpose of a negative pressure room is to confine pathogens to a single closed environment and to prevent the release of pathogens into other adjacent spaces.

### Demographics

Official counts of negative pressure rooms do not exist. Experts estimate that approximately 4000-5000 negative pressure rooms exist in hospitals throughout the United States.

### Description

A negative pressure room is designed to confine pathogens to a small volume of space. It is also intended to prevent the accidental release of pathogens into a greater space thereby protecting workers and employees in a hospital or other healthcare facility.

All communications between a negative pressure room and adjacent spaces are controlled. Communications include doors and ventilations ducts. These are sealed. Air flow is controlled by airlocks for human travel and vacuum pumps for ventilation systems.

### Diagnosis/Preparation

Negative pressure rooms require special construction. All points of entrance or egress must be able to be tightly sealed so that air cannot pass by the seals. The room ventilation system must be equipped with a vacuum pump that must create a constant but relatively low level vacuum. This creates the negative pressure.

In operation, the vacuum created stops the outflow of air, thus containing

Two doors, separated by at least 6 feet, must be installed to create an airlock. Only one door is opened at a time. This preserves the vacuum, maintains the negative pressure and prevents pathogens from escaping.

## QUESTIONS TO ASK YOUR DOCTOR

- Why am I being confined in a negative pressure room?
- What treatment options do I have?

All air exhausted from the room is routed through special filters that are designed to trap and contain pathogens.

Negative pressure rooms are used when the presence of an airborne pathogen such as tuberculosis is suspected.

### Aftercare

Entrance and egress protocols must be followed by all people that enter or leave a negative pressure room.

Seals on vents and airlocks must be checked on a regular basis.

Negative pressure rooms must be decontaminated before being cleaned after being occupied.

### Risks

Seal, pump or protocol failure destroys the negative pressure and increases the chances that pathogens will be released.

Inadequate cleaning after occupancy puts subsequent occupants at risk of exposure to a potentially dangerous pathogen.

### Normal results

In a properly operating negative pressure room, the expected and normal result is containment of a potentially dangerous pathogen.

### Morbidity and mortality rates

Data on morbidity and mortality related to negative pressure rooms is not available.

### Alternatives

The only feasible alternative to a negative pressure room is quarantine and isolation. This practice is very difficult to enforce. Even when enforced, it is not as microbiologically efficient.

## KEY TERMS

**Anthrax**—A dangerous pathogen that should be contained in a negative pressure room.

**Ebola virus** —A dangerous pathogen that should be contained in a negative pressure room.

**Tuberculosis**—A dangerous pathogen that should be contained in a negative pressure room.

## Nephrectomy

### Definition

A nephrectomy is a surgical procedure for the removal of a kidney or section of a kidney.

### Purpose

Nephrectomy, or kidney removal, is performed on patients with severe kidney damage from disease, injury, or congenital conditions. These include cancer of the kidney (renal cell carcinoma); polycystic kidney disease (a disease in which cysts, or sac-like structures, displace healthy kidney tissue); and serious kidney infections. It is also used to remove a healthy kidney from a donor for the purposes of **kidney transplantation**.

### Demographics

The HCUP Nationwide Inpatient Sample from the Agency for Healthcare Research and Quality (AHRQ) reports that 46,130 patients underwent partial or radical nephrectomy surgery for non-transplant-related indications in the United States in 2000. Patients with kidney cancer accounted for over half of those procedures. About 51,190 new cases of renal cell

## Nephrectomy

To remove a kidney in an open procedure, an incision is made below the ribcage (A). The kidney is exposed (B) and connections to blood vessels and the ureter are severed (C). The kidney is removed in one piece (D). (Illustration by GGS Information Services. Cengage Learning, Gale.)

carcinoma were expected to be diagnosed in 2007, per the American Cancer Society.

According to the United Network for Organ Sharing (UNOS), 5,086 people underwent nephrectomy to become living kidney donors in 2007. Of these, 2,911 were male and 2,975 were female. Related donors were more common than non-related donors, with full siblings being the most common relationship

between living donor and kidney recipients (28.5% of living donors).

### Description

Nephrectomy may involve removing a small portion of the kidney or the entire organ and surrounding tissues. In partial nephrectomy, only the diseased or

## KEY TERMS

**Cadaver kidney**—A kidney from a brain-dead organ donor used for purposes of kidney transplantation.

**Polycystic kidney disease**—A hereditary kidney disease that causes fluid- or blood-filled pouches of tissue called cysts to form on the tubules of the kidneys. These cysts impair normal kidney function.

**Renal cell carcinoma**—Cancer of the kidney.

infected portion of the kidney is removed. Radical nephrectomy involves removing the entire kidney, a section of the tube leading to the bladder (ureter), the gland that sits atop the kidney (adrenal gland), and the fatty tissue surrounding the kidney. A simple nephrectomy performed for living donor transplant purposes requires removal of the kidney and a section of the attached ureter.

### *Open nephrectomy*

In a traditional, open nephrectomy, the kidney donor is administered **general anesthesia** and a 6–10 in (15.2–25.4 cm) incision through several layers of muscle is made on the side or front of the abdomen. The blood vessels connecting the kidney to the donor are cut and clamped, and the ureter is also cut between the bladder and kidney and clamped. Depending on the type of nephrectomy procedure being performed, the ureter, adrenal gland, and/or surrounding tissue may also be cut. The kidney is removed and the vessels and ureter are then tied off and the incision is sutured (sewn up). The surgical procedure can take up to three hours, depending on the type of nephrectomy being performed.

### *Laparoscopic nephrectomy*

Laparoscopic nephrectomy is a form of minimally invasive surgery that utilizes instruments on long, narrow rods to view, cut, and remove the kidney. The surgeon views the kidney and surrounding tissue with a flexible videoscope. The videoscope and **surgical instruments** are maneuvered through four small incisions in the abdomen, and carbon dioxide is pumped into the abdominal cavity to inflate it and improve visualization of the kidney. Once the kidney is isolated, it is secured in a bag and pulled through a fifth incision, approximately 3 in (7.6 cm) wide, in the front of the abdominal wall below the navel. Although this surgical technique takes slightly longer than a traditional nephrectomy, preliminary studies have

shown that it promotes a faster recovery time, shorter hospital stays, and less post-operative pain.

A modified laparoscopic technique called hand-assisted laparoscopic nephrectomy may also be used to remove the kidney. In the hand-assisted surgery, a small incision of 3–5 in (7.6–12.7 cm) is made in the patient's abdomen. The incision allows the surgeon to place his hand in the abdominal cavity using a special surgical glove that also maintains a seal for the inflation of the abdominal cavity with carbon dioxide. This technique gives the surgeon the benefit of using his hands to feel the kidney and related structures. The kidney is then removed by hand through the incision instead of with a bag.

## Diagnosis/Preparation

Prior to surgery, blood samples will be taken from the patient to type and crossmatch in case **transfusion** is required during surgery. A catheter will also be inserted into the patient's bladder. The surgical procedure will be described to the patient, along with the possible risks.

## Aftercare

Nephrectomy patients may experience considerable discomfort in the area of the incision. Patients may also experience numbness, caused by severed nerves, near or on the incision. Pain relievers are administered following the surgical procedure and during the recovery period on an as-needed basis. Although deep breathing and coughing may be painful due to the proximity of the incision to the diaphragm, breathing exercises are encouraged to prevent pneumonia. Patients should not drive an automobile for a minimum of two weeks.

## Risks

Possible complications of a nephrectomy procedure include infection, bleeding (hemorrhage), and post-operative pneumonia. There is also the risk of kidney failure in a patient with impaired function or disease in the remaining kidney.

## Normal results

Normal results of a nephrectomy are dependent on the purpose of the procedure and the type of nephrectomy performed. Immediately following the procedure, it is normal for patients to experience pain near the incision site, particularly when coughing or breathing deeply. Renal function of the patient is monitored carefully after surgery. If the remaining kidney is

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

If nephrectomy is required for the purpose of kidney donation, it will be performed by a transplant surgeon in one of over 200 UNOS-approved hospitals nationwide. For patients with renal cell carcinoma, nephrectomy surgery is typically performed in a hospital setting by a surgeon specializing in urologic oncology.

healthy, it will increase its functioning over time to compensate for the loss of the removed kidney.

Length of hospitalization depends on the type of nephrectomy procedure. Patients who have undergone a laparoscopic radical nephrectomy may be discharged two to four days after surgery. Traditional open nephrectomy patients are typically hospitalized for about a week. Recovery time will also vary, on average from three to six weeks.

### Morbidity and mortality rates

Survival rates for living kidney donors undergoing nephrectomy are excellent; mortality rates are only 0.03%—or three deaths for every 10,000 donors. Many of the risks involved are the same as for any surgical procedure: risk of infection, hemorrhage, blood clot, or allergic reaction to anesthesia.

For patients undergoing nephrectomy as a treatment for renal cell carcinoma, survival rates depend on several factors, including the stage of the cancer and the patient's overall **health history**. According to the American Cancer Society, the five-year survival rate for patients with stage I renal cell carcinoma is 96 percent, while the five-year survival rate for stage II kidney cancer is 82 percent. Stage III and IV cancers have metastasized, or spread, beyond the kidney and have a lower survival rate, 64 percent for stage III and about 23 percent for stage IV. Chemotherapy, radiation, and/or immunotherapy may also be required for these patients.

### Alternatives

Because the kidney is responsible for filtering wastes and fluid from the bloodstream, kidney function is critical to life. Nephrectomy candidates diagnosed with serious kidney disease, cancer, or infection usually have few treatment choices aside from this

## QUESTIONS TO ASK THE DOCTOR

- How many procedures of this type have you performed, and what are your success rates?
- Will my nephrectomy surgery be performed with a laparoscopic or an open technique?
- Will my nephrectomy be partial or radical, and what are the risks involved with my particular surgery?
- What will my recovery time be after the procedure?
- What are the chances that the transplant will be successful? (For those undergoing a nephrectomy to donate a kidney.)
- What are the odds of success, and will I require adjunctive treatment such as chemotherapy or immunotherapy? (For those undergoing a nephrectomy to treat kidney cancer.)

procedure. However, if kidney function is lost in the remaining kidney, the patient will require chronic dialysis treatments or transplantation of a healthy kidney to sustain life.

## Nephrolithotomy, percutaneous

### Definition

Percutaneous nephrolithotomy, or PCNL, is a procedure for removing medium-sized or larger renal calculi (kidney stones) from the patient's urinary tract by means of a nephroscope passed into the kidney through a track created in the patient's back. PCNL was first performed in Sweden in 1973 as a less invasive alternative to open surgery on the kidneys. The term "percutaneous" means that the procedure is done through the skin. Nephrolithotomy is a term formed from two Greek words that mean "kidney" and "removing stones by cutting."

### Purpose

The purpose of PCNL is the removal of renal calculi in order to relieve pain, bleeding into or obstruction of the urinary tract, and/or urinary tract infections resulting from blockages. Kidney stones range in size from microscopic groups of crystals to objects as large as golf balls. Most calculi, however, pass through the urinary tract without causing problems.

**Intravenous pyelogram (IVP) of kidneys, ureters, and urinary bladder.** (Scott Camazine / Phototake. Reproduced by permission.)

Renal calculi are formed when the urine becomes supersaturated (overloaded) with mineral compounds that can form stones. This supersaturation may occur because the patient has low urinary output, is excreting too much salt, or has very acid urine. Urolithiasis is the medical term for the formation of kidney stones; the word is also sometimes used to refer to disease conditions associated with kidney stones.

There are several different types of kidney stones, in terms of chemical composition:

- **Calcium oxalate calculi.** About 80% of calculi found in patients in the United States are formed from calcium combined with oxalate, which is a salt formed from oxalic acid. Some foods, such as rhubarb and spinach, are high in oxalic acid. Oxalic acid is also formed in the body when vitamin C is broken down. Oxalic acid is ordinarily excreted through the urine but may be absorbed in large amounts due to chronic pancreatic disease or surgery involving the small intestine.
- **Uric acid calculi.** These stones develop from crystals of uric acid that form in highly acidic urine. Uric acid calculi account for about 5% of kidney stones. In addition, some kidney stones are a combination of calcium oxalate and uric acid crystals.
- **Cystine calculi.** Cystine calculi represent about 2% of kidney stones. Cystine is an amino acid found in proteins that may form hexagonal crystals in the urine when it is excreted in excessive amounts. Kidney stones made of cystine indicate that the patient has cystinuria, a hereditary condition in which the kidneys do not reabsorb this amino acid.
- **Struvite calculi.** Struvite is a hard crystalline form of magnesium aluminum phosphate. Kidney stones made of this substance are formed in patients with urinary tract infections caused by certain types of bacteria. Struvite calculi are also known as infection calculi for this reason.
- **Staghorn calculi.** Staghorn calculi are large branched calculi composed of struvite. They are often discussed separately because their size and shape complicate their removal from the urinary tract.

Some people are more likely than others to develop renal calculi. Risk factors for kidney stones include:

- Male sex.
- Family history. Having a first-degree relative with urolithiasis increases a person's risk of developing kidney stones.
- Age over 30.

# Percutaneous nephrolithotomy

During a percutaneous nephrolithotomy, the surgeon inserts a needle through the patient's back directly into the kidney (B). A nephroscope uses an ultrasonic or laser probe to break up large kidney stones (C). Pieces of the stones are suctioned out with the scope, and a nephrostomy tube drains the kidney of urine (D). (Illustration by GGS Information Services. Cengage Learning, Gale.)

- **Diet.** People whose diet is high in protein or who eat foods rich in oxalate are more likely to develop kidney stones.
- **Dehydration.** People who do not drink enough fluid each day to replace what is lost through perspiration and excretion produce very concentrated urine. It is

## KEY TERMS

**Bougie**—A slender, flexible tube or rod inserted into the urethra in order to dilate it.

**Calculus (plural, calculi)**—The medical term for a kidney or gallbladder stone.

**Cystine**—An amino acid found in protein molecules that may form kidney stones when excreted in excessive amounts in the urine.

**Cystinuria**—A hereditary condition characterized by chronic excessive excretion of cystine and three other amino acids.

**Infection calculi**—Another name for struvite calculi.

**Lithotripsy**—A technique for breaking up kidney stones within the urinary tract, followed by flushing out the fragments.

**Nephrolithotomy**—The removal of renal calculi by an incision through the kidney. The term by itself usually refers to the standard open procedure for the surgical removal of kidney stones.

**Nephroscope**—An instrument used to view the inside of the kidney during PCNL. A nephroscope has channels for a fiberoptic light, a telescope, and an irrigation system for washing out the affected part of the kidney.

**Percutaneous**—Through the skin.

**Staghorn calculus**—A kidney stone that develops a branched shape resembling the antlers of a stag. Staghorn calculi are composed of struvite.

**Struvite**—A crystalline form of magnesium ammonium phosphate. Kidney stones made of struvite form in urine with a pH above 7.2.

**Ureter**—The tubelike structure that carries urine from the kidney to the bladder.

**Ureteroscope**—A special type of endoscope that allows a surgeon to remove kidney stones from the lower urinary tract without the need for an incision.

**Urolithiasis**—The medical term for the formation of kidney stones. It is also used to refer to disease conditions related to kidney stones.

easier for crystals to form in concentrated than in dilute urine, and to grow into kidney stones.

- Metabolic disorders affecting the body's excretion of salt or its absorption of calcium or oxalate. Most cases of urolithiasis in children are related to metabolic disorders.
- Intestinal bypass surgery and ostomies. People who have had these surgical procedures lose larger than average amounts of water from the digestive tract.

## Demographics

Calculi in the urinary tract are common in the general United States population. Between seven and 10 of every 1,000 hospitalizations each year are due to urolithiasis; in addition, kidney stones are found in about 1% of bodies at autopsy. An estimated 10% of the population will suffer from kidney stones at some point in life. 12% of men and 6% of women will have kidney stones at some point over the course of their lifetimes.

In terms of age groups, most people with urolithiasis are between the ages of 20 and 40; kidney stones are rare in children. A person who develops one kidney stone has a 50% chance of developing another.

With regard to race, Caucasians are more likely to develop kidney stones than African Americans.

## Description

### Standard PCNL

A standard percutaneous nephrolithotomy is performed under **general anesthesia** and usually takes about three to four hours to complete. After the patient has been anesthetized, the surgeon makes a small incision, about 0.5 in (1.3 cm) in length in the patient's back on the side overlying the affected kidney. The surgeon then creates a track from the skin surface into the kidney and enlarges the track using a series of Teflon dilators or bougies. A sheath is passed over the last dilator to hold the track open.

After the track has been enlarged, the surgeon inserts a nephroscope, which is an instrument with a fiberoptic light source and two additional channels for viewing the inside of the kidney and irrigating (washing out) the area. The surgeon may use a device with a basket on the end to grasp and remove smaller kidney stones directly. Larger stones are broken up with an ultrasonic or electrohydraulic probe, or a holmium laser lithotripter. The holmium laser has the advantage of being usable on all types of calculi.

A catheter is placed to drain the urinary system through the bladder and a **nephrostomy** tube is placed in the incision in the back to carry fluid from the kidney into a drainage bag. The catheter is removed after 24

hours. The nephrostomy tube is usually removed while the patient is still in the hospital but may be left in after the patient is discharged.

### *Mini-percutaneous nephrolithotomy*

A newer form of PCNL is called mini-percutaneous nephrolithotomy (MPCNL) because it is performed with a miniaturized nephroscope. MPCNL has been found to be 99% effective in removing calculi between 0.4 and 1 in (1 and 2.5 cm) in size. Although it cannot be used for larger kidney stones, MPCNL has the advantage of fewer complications, a shorter operating time (about one and a half hours), and a shorter recovery time for the patient.

## Diagnosis/Preparation

### *Diagnosis*

Kidney stones may be discovered during a routine x-ray study of the patient's abdomen. These stones, which would ordinarily pass through the urinary tract unnoticed, are sometimes referred to as silent stones. In most cases, however, the patient seeks medical help for sudden intense pain in the lower back, usually on the side of the affected kidney. The pain is caused by the movement of the stone in the urinary tract as it irritates the tissues or blocks the passage of urine. If the stone moves further downward into the ureter (the tube that carries urine from the kidney to the bladder), pain may spread to the abdomen and groin area. The patient may also have nausea and vomiting, blood in the urine, pain on urination, or a need to urinate frequently. If the stone is associated with a UTI, the patient may also have chills and fever. The doctor will order both laboratory studies and imaging tests in order to rule out such other possible causes of the patient's symptoms as appendicitis, pancreatitis, peptic ulcer, and dissecting aneurysm.

The imaging studies most commonly performed are x ray and **ultrasound**. Pure uric acid and cystine calculi, however, do not show up well on a standard x ray, so the doctor may also order an intravenous pyelogram, or IVP. In an IVP, the radiologist injects a radioactive contrast material into a vein in the patient's arm, and records its passage through the urinary system in a series of x-ray images. Blood and urine samples will be taken to test for indications of a urinary tract infection. If the patient passes the kidney stone, it is saved and sent to a laboratory for analysis.

### *Preparation*

Most hospitals require patients to have the following tests before a PCNL: a complete **physical examination**;

**complete blood count**; an **electrocardiogram** (EKG); a comprehensive set of metabolic tests; a urine test; and tests that measure the speed of blood clotting.

**Aspirin** and arthritis medications should be discontinued seven to 10 days before a PCNL because they thin the blood and affect clotting time. Some surgeons ask patients to take a laxative the day before surgery to minimize the risk of constipation during the first few days of recovery.

The patient is asked to drink only clear fluids (chicken or beef broth, clear fruit juices, or water) for 24 hours prior to surgery, with nothing by mouth after midnight before the procedure.

## Aftercare

A standard PCNL usually requires hospitalization for five to six days after the procedure. The urologist may order additional imaging studies to determine whether any fragments of stones are still present. These can be removed with a nephroscope if necessary. The nephrostomy tube is then removed and the incision covered with a bandage. The patient will be given instructions for changing the bandage at home.

The patient is given fluids intravenously for one to two days after surgery. Later, he or she is encouraged to drink large quantities of fluid in order to produce about 2 qt (1.2 l) of urine per day. Some blood in the urine is normal for several days after PCNL. Blood and urine samples may be taken for laboratory analysis of specific risk factors for calculus formation.

## Risks

There are a number of risks associated with PCNL:

- Inability to make a large enough track to insert the nephroscope. In this case, the procedure will be converted to open kidney surgery.
- Bleeding. Bleeding may result from injury to blood vessels within the kidney as well as from blood vessels in the area of the incision.
- Infection.
- Fever. Running a slight temperature (101.5°F; 38.5°C) is common for one or two days after the procedure. A high fever or a fever lasting longer than two days may indicate infection, however, and should be reported to the doctor at once.
- Fluid accumulation in the area around the incision. This complication usually results from irrigation of the affected area of the kidney during the procedure.
- Formation of an arteriovenous fistula. An arteriovenous fistula is a connection between an artery and

a vein in which blood flows directly from the artery into the vein.

- Need for retreatment. In general, PCNL has a higher success rate of stone removal than extracorporeal shock wave lithotripsy (ESWL), which is described below. PCNL is considered particularly effective for removing stones larger than 1 in (0.5 cm); staghorn calculi; and stones that have remained in the body longer than four weeks. Retreatment is occasionally necessary, however, in cases involving very large stones.
- Injury to surrounding organs. In rare cases, PCNL has resulted in damage to the spleen, liver, lung, pancreas, or gallbladder.

### Normal results

PCNL has a high rate of success for stone removal, over 98% for stones that remain in the kidney and 88% for stones that pass into the ureter.

### Morbidity and mortality rates

Standard PCNL has a higher rate of complications than extracorporeal shock wave **lithotripsy**; however, it is more successful in removing calculi. The overall rate of complications following PCNL is reported as 5.6% in one recent study and 6.5% in a second article. About 20% of patients scheduled for PCNL require a blood **transfusion** during the procedure, with 2.8% needing treatment for bleeding after the procedure. The rate of fistula formation is about 2.5%.

### Alternatives

Patients with kidney stones may be treated with one or more of the following procedures in addition to PCNL, depending on the size of their renal calculi and possible complications. One frequently used combination, known as sandwich therapy, is extracorporeal shock wave lithotripsy for smaller stones followed by PCNL to remove larger calculi.

#### *Conservative approaches*

Conservative forms of treatment include the following:

- Watchful waiting.
- Hydration. Increasing the patient's fluid intake (to seven or more glasses of fluid each day) is a major component of treatment intended to prevent the formation of kidney stones. At least half of the fluid should be water.
- Dietary modification. Depending on the type of stone that has formed, the patient may benefit from

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

A PCNL or mini-PCNL is performed under general anesthesia in a hospital by a urologist, who is a surgeon with specialized training in treating disorders of the urinary tract. ESWL may be done as an outpatient procedure in an ambulatory surgery facility.

eating less animal protein, avoiding vegetables with high oxalate content, cutting down on table salt and vitamin C intake, etc.

- Medications. Patients who tend to form uric acid stones may be given allopurinol, which decreases the formation of uric acid; those who form calcium oxalate stones may be given thiazide diuretics; and those who develop infection stones can be treated with oral antibiotics.

#### *Open surgery*

Open surgery is the most invasive form of treatment for urolithiasis. As of 2003, it is performed primarily to remove very large and complex staghorn calculi or extremely hard stones that cannot be broken down by lithotripsy. Other indications for open surgery are extreme obesity, an anatomically abnormal kidney, or an infected and nonfunctioning kidney requiring complete removal. Patients are usually hospitalized for a week after open kidney surgery and take about six weeks to recover at home.

#### *Extracorporeal shock wave lithotripsy (ESWL)*

ESWL is a noninvasive procedure that was developed in the 1980s as a less invasive alternative to PCNL. It is presently used more often than PCNL to treat smaller renal calculi. In ESWL, the patient is given a local anesthetic and placed in a water bath or on a soft cushion while shock waves are transmitted through the tissues of the back to the stones inside the kidney. The shock waves cause the calculi to break up into smaller pieces that can be passed easily in the urine.

Although patients need less time to recuperate from ESWL, it has several disadvantages. It has lower success rates (50–90%) than PCNL. Moreover, it cannot be used to treat cystine calculi or calculi larger than 1.2 in (3 cm). An additional concern with shock wave lithotripsy is its safety in treating small or anatomically abnormal kidneys; it has been reported

## QUESTIONS TO ASK THE DOCTOR

- Am I a candidate for a mini-PCNL?
- Do you consider the higher success rate of a PCNL a greater advantage than the lower rate of complications with ESWL?
- What can I do to prevent recurrence of kidney stones?
- What are the chances of my needing another operation?

to cause temporary damage to kidney tubules in smaller-than-average kidneys.

### Ureteroscopy

Ureteroscopy refers to removal of calculi that have moved downward into the ureter with the help of a special instrument. A ureteroscope is a small fiberoptic endoscope that can be passed through the patient's urethra and bladder into the ureter. The ureteroscope allows the surgeon to locate and remove stones in the lower urinary tract without the need for an incision.

### Complementary and alternative (CAM) approaches

Vegetarian and other low-protein diets have been found helpful in preventing kidney stone formation. In addition, recent ethnobotanical studies of ammi visnaga (toothpick weed), a plant belonging to the parsley family, and *Phyllanthus niruri*, a traditional Brazilian folk remedy for kidney stones, indicate that extracts from these plants are effective in increasing urinary output and inhibiting the development of calcium oxalate calculi.

## Nephrostomy

### Definition

A nephrostomy is a surgical procedure by which a tube, stent, or catheter is inserted through the skin and into the kidney.

### Purpose

The ureter is the fibromuscular tube that carries urine from the kidney to the bladder. When this tube is blocked, urine backs up into the kidney. Serious, irreversible kidney damage can occur because of this backflow of urine. Infection is also a common consequence in this stagnant urine.

Nephrostomy is performed in several different circumstances:

- The ureter is blocked by a kidney stone.
- The ureter is blocked by a tumor, abscess, or fluid collection.
- There is a hole in the ureter or bladder and urine is leaking into the body. These may occur after trauma

## KEY TERMS

**Catheter**—A tubular, flexible, surgical instrument for withdrawing fluids from a cavity of the body, especially one for introduction into the bladder through the urethra for the withdraw of urine.

**Ostomy**—General term meaning a surgical procedure in which an artificial opening is formed to either allow waste (stool or urine) to pass from the body, or to allow food into the GI tract. An ostomy can be permanent or temporary, as well as single-barreled, double-barreled, or a loop.

**Septicemia**—Systemic disease associated with the presence and persistence of pathogenic microorganisms or their toxins in the blood.

**Stent**—A tube made of metal or plastic that is inserted into a vessel or passage to keep it open and prevent closure.

**Ureter**—The fibromuscular tube that conveys the urine from the kidney to the bladder.

or accidental injury during surgery (iatrogenic injury), or severe hemorrhagic cystitis.

- The ureter is obstructed during pregnancy.
- Access is needed in order to infuse materials/medications directly into the kidney, such as antibiotics, antifungal agents, chemotherapeutic agents, or chemicals that will dissolve stones.
- As a diagnostic procedure to assess kidney anatomy.
- As a diagnostic procedure to assess kidney function.

## Demographics

For unknown reasons, the number of people in the United States with kidney and ureter stones has been increasing over the past 20 years. White Americans are more prone to develop kidney stones than African Americans. Stones occur more frequently in men. The condition strikes most typically between the ages of 20 and 40. Once a person gets more than one stone, others are likely to develop.

Upper tract tumors develop in the renal pelvis (tissue in the kidneys that collects urine) and in the ureters. These cancers account for less than 1% of cancers of the reproductive and urinary systems. Upper tract tumors are often associated with bladder cancer.

## Description

First, the patient is given an anesthetic to numb the area where the catheter will be inserted. The doctor then inserts a needle into the kidney. There are several imaging technologies such as **ultrasound** and computed tomography (CT) that are used to help the doctor guide the needle into the correct place.

Next, a fine guide wire follows the needle. The catheter, which is about the same diameter as intravenous (IV) tubing, follows the guide wire to its proper location. The catheter is then connected to a bag outside the body that collects the urine. The catheter and bag are secured so that the catheter will not pull out. The procedure usually takes one to two hours.

## Diagnosis/Preparation

Either the day before or the day of the nephrostomy, blood samples are taken. Other diagnostic tests done before the procedure may vary, depending on why the nephrostomy is being done, but the patient may have a CT scan or ultrasound to help the treating physician locate the blockage.

Patients should not eat for eight hours before a nephrostomy. On the day of the procedure, the patient will have an IV line placed in a vein in the arm. Through this line, the patient will receive **antibiotics** to prevent infection, medication for pain, and fluids. The IV line will remain in place after the procedure for at least several hours, and often longer.

People preparing for a nephrostomy should review with their doctor all the medications they are taking. People taking anticoagulants (blood thinners such as Coumadin) may need to stop their medication. People taking metformin (Glucophage) may need to stop taking the medication for several days before and after nephrostomy. Diabetics should discuss modifying their insulin dose because fasting is required before the procedure.

## Aftercare

Outpatients are usually expected to stay in the clinic or hospital for eight to 12 hours after the procedure to make sure the nephrostomy tube is functioning properly. They should plan to have someone drive them home and stay with them for at least the first 24 hours after the procedure. Inpatients may stay in the hospital several days. Generally, people feel sore where the catheter is inserted for about a week to 10 days.

Care of the nephrostomy tube is important. It is located on the patient's back, so it may be necessary to have someone help with its care. The nephrostomy

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

A nephrostomy is performed by an interventional radiologist or urologist with special training in the procedure. It can be done either on an inpatient or outpatient basis, depending on why it is required. For most cancer patients, nephrostomy is an inpatient procedure. Specially trained nurses called wound, ostomy continence nurses (WOCN) are commonly available for consultation in most major medical centers to assist patients.

tube should be kept dry and protected from water when taking showers. The skin around it should be kept clean, and the dressing over the area changed frequently. It is the main part of the urine drainage system, and it should be treated very carefully to prevent bacteria and other germs from entering the system. If any germs get into the tubing, they can easily cause a kidney infection. The drainage bag should not be allowed to drag on the floor. If the bag should accidentally be cut or begin to leak, it must be changed immediately. It is not recommended to place the drainage bag in a plastic bag if it leaks.

### Risks

A nephrostomy is an established and generally safe procedure. As with all operations, there is always a risk of allergic reaction to anesthesia, bleeding, and infection.

Bruising at the catheter insertion site occurs in about half of people who have a nephrostomy. This is a minor complication. Major complications include the following:

- injury to surrounding organs, including bowel perforation, splenic injury, and liver injury
- infection, leading to septicemia
- significant loss of functioning kidney tissue (<1%)
- delayed bleeding, or hemorrhage (<0.5%)
- blocking of a kidney artery (<0.5%)

### Normal results

In a successful nephrostomy, the catheter is inserted, and urine drains into the collection bag. How long the catheter stays in place depends on the reason for its insertion. In people with pelvic cancer or bladder cancer where the ureter is blocked by a

## QUESTIONS TO ASK THE DOCTOR

- Why am I having a nephrostomy?
- How do I prepare for surgery?
- How long will I have to stay in the hospital?
- How long do you expect the nephrostomy tube to stay in?
- How much help will I need in caring for the nephrostomy tube?

tumor, the catheter will stay in place until the tumor is surgically removed. If the cancer is inoperable, the catheter may have to stay in place for the rest of the patient's life.

### Morbidity and mortality rates

The mortality rate of nephrostomies is of the order of less than 0.05% and the incidence of the specific complications listed above ranges between less than 0.05% (hemorrhage, kidney arterial blocking, and loss of kidney tissue) to <1% (injury to surrounding organs and septicemia).

### Alternatives

In the treatment of ureter stones, extracorporeal shock wave **lithotripsy** (ESWL) has been most widely performed and has become the preferred treatment for this condition. ESWL is a new technique that offers an alternative to surgery for patients with kidney or ureter stones. ESWL works by pulverizing the stones into sand-like particles that can be excreted with little or no pain. This is achieved by the ESWL procedure approximately 90% of the time. The shock waves are a form of high-energy pressure that can travel in air or water. When generated outside the body, they pass through the tissues of the body without damaging them, but can destroy a stone inside a kidney or urethra. The shock waves pass through both without injury. A stone has a greater density and, when the shock wave hits it, the waves scatter and break it up.

## Neurosurgery

### Definition

Neurosurgery is a specialized field of surgery for the treatment of diseases or conditions of the central nervous system (CNS) and spine.

### Description

Neurosurgery is the specialized field of surgery that treats diseases that affect the CNS—the brain and the spine. A neurosurgeon is a medical doctor who has received extensive training in the surgical and medical management of neurological diseases. The field of neurosurgery is one of the most sophisticated surgical specialties and encompasses advanced surgical and imaging technology and new research in molecular neurosurgery and gene therapy. There are five general categories of neurosurgical diseases that are commonly managed by neurosurgeons: cerebrovascular (hemorrhage [bleeding] and aneurysms); traumatic head injury (THI, traumatic injury caused by accident); degeneration diseases of the spine; tumors in the CNS; functional neurosurgery; surgery for congenital abnormalities; and neurosurgical management of the CNS.

Cerebrovascular diseases that usually require surgery include spontaneous intracranial hemorrhage (bleeding within the skull), spontaneous subarachnoid hemorrhage (bleeding beneath the outer membranous covering of the brain), spontaneous intracerebral hemorrhage (bleeding within the brain), cerebral aneurysms (outpouchings of the blood vessel), hypertensive intracerebral hemorrhage (due to high blood pressure), and angiomatous malformations.

### Brain hemorrhage

Spontaneous intracranial hemorrhage is a condition characterized by hemorrhage in the brain (hemorrhagic stroke) that results in a sudden onset of neurologically worsening symptoms (that include focal neurologic deficits and loss of consciousness). **CT scans** are helpful in identifying the intracranial hemorrhage, of which there are two types—subarachnoid hemorrhage and intracerebral hematoma.

The subarachnoid space is an area that exists between two layers of coverings (membranes) that wrap around the brain. A spontaneous subarachnoid hemorrhage is defined as blood (not caused by trauma), in the subarachnoid space. The amount of blood in the subarachnoid space can be a focal (small area) amount or a larger, more diffuse hemorrhage, which can be further complicated by having an intraventricular hemorrhage or intracerebral hematoma at the same time.

The incidence of subarachnoid hemorrhage is 10 per 100,000 persons per year; approximately 30% of Americans will sustain a subarachnoid hemorrhage annually. Smoking is a major factor in increasing the odds of sustaining a subarachnoid hemorrhage.

## KEY TERMS

**Angiomatous malformations**—Tumors in blood vessels.

**Cerebral aneurysms**—A sac in a blood vessel in the brain that can rupture and cause bleeding in the brain.

**Craniosynostosis**—Premature closure of the skull, which results in skull deformities.

**Craniotomy**—Procedure to remove a lesion in the brain through an opening in the skull.

**Desiccation**—Tissue death.

**Encephaloceles**—Protrusion of the brain through a defect in the skull.

**Germinoma**—A tumor of germ cells (ovum and sperm cells that participate in production of the developing embryo).

**Hydrocephalus**—A defect characterized by an increase in cerebrospinal fluid (CSF), which bathes and nourishes the brain and spinal cord.

**Intraventricular hemorrhage**—Hemorrhage in the ventricles of the brain.

**Lymphoma**—A tumor of lymph glands or lymph tissues.

**Meninges**—Membranes that cover the brain.

**Myelomeningoceles (MMC)**—A protrusion in the vertebral column containing spinal cord and meninges.

**Subarachnoid space**—A space between membranes that covers and protects the brain.

Subarachnoid hemorrhage can affect adults of all ages, but usually peaks in the fourth and fifth decades of life. Approximately 60% of patients are female. Approximately 30% of subarachnoid hemorrhages occur during sleep.

The most frequent cause of spontaneous subarachnoid hemorrhage is rupture of an intracranial aneurysm. The symptoms of subarachnoid hemorrhage are a sudden onset of severe headache that worsens over time, nausea, loss of consciousness (with or without seizure), and vomiting. Depending on the severity of bleeding, additional symptoms can also include visual sensitivity to light (photophobia), a stiff neck, and minor (low-grade) fever. Symptoms occur before rupture of the aneurysm in 40% of patients, usually in those with a minor hemorrhage. These symptoms can also include headache or dizziness, and tend to go unnoticed.

After a subarachnoid hemorrhage, most patients are hypertensive (have high blood pressure) and experience changes in heart rate and rhythm. CT scans are the best diagnostic tool for subarachnoid hemorrhage. The hemorrhage can be visualized in the first 24 hours after onset in 90% of patients and in more than 50% in the first week. Spinal taps to sample the cerebrospinal fluid (CSF) may be required to evaluate some patients who have the potential to suffer a subarachnoid hemorrhage. This procedure involves the insertion of a thin needle between the lumbar vertebral bodies (L-4 and L-5) to allow the removal of a small amount of fluid to look for either red or white blood cells (WBCs). Once the aneurysm has been identified, the patient is taken for surgery. A **craniotomy** is performed using microsurgical techniques. The operative microscope helps to identify the aneurysm, which is then clipped. Berry, or congenital aneurysm, is the reason for over half of all cases of spontaneous subarachnoid hemorrhage.

A spontaneous intracerebral hemorrhage (or hematoma) (SICH) is a blood clot in brain tissue that can arise abruptly and is strongly correlated with hypertension. There are approximately 40,000 new cases of SICH in the United States annually. Stroke is the third leading cause of **death** in the United States, and SICH accounts for 10% of all stroke cases. Advancing age is a major predisposing factor for SICH: The incidence of SICH is two per 1,000 persons per year by age 45, and rises to 350 per 100,000 persons per year in those aged 80 years or more. Hypertensive intracerebral hemorrhage can occur in different areas within the brain. Damage to some areas may be associated with a very high death rate. Treatment includes comprehensive ICU (**intensive care unit**) management of hypertension and maintenance of adequate cerebral perfusion (oxygenated blood going to the brain).

Accidental head injury is a major public health problem. Trauma causes approximately 150,000 deaths annually in the United States; approximately half of these deaths were caused by fatal head trauma. Additionally, there are 10,000 new spinal cord injuries annually. The cost of disability (e.g., chronic long-term care, lost wages, and work) is very high. Approximately 200,000 persons in the United States are living with disabilities associated with head and spinal cord trauma.

Severe head injury is defined as an injury that produces coma (patient will not open eyes even to painful stimulus; incapable of following simple commands; and inability to utter words). These clinical criteria are defined on the well-established Glasgow Coma Scale (GCS). A **physical examination** and neurologic assessment by a neurosurgeon and brain scan

imaging (CT scan) are necessary for the initial evaluation. Additionally, a special catheter to monitor intracranial pressure (due to brain swelling) is necessary. A blood clot larger than 25 to 30 cubic centimeters is considered clinically large enough to cause progressive brain injury.

Tumors inside the brain (intracranial tumors) are typically of two types, primary and secondary intracranial tumors. Primary intracranial tumors (PICT) rarely metastasize and usually originate in the brain, coverings (membranes) of the brain, or the pituitary gland. The incidence of primary intracranial tumors is 11.5 per 100,000, or approximately 35,000 persons per year.

Secondary intracranial tumors arise from outside the brain coverings (meninges). Quite commonly, secondary intracranial tumors are bloodborne metastatic disease from primary malignant cancer outside the brain (i.e., cancer from some other location that has spread to the brain). Approximately 250,000 persons per year are affected by secondary intracranial tumors. A tumor in the brain can cause increased intracranial pressure, or cause symptoms associated with localized compression of the brain (i.e., a tumor grows and compresses part of the brain against the skull). One common cause of increased intracranial pressure is growth of a tumor that obstructs the duct system of cerebrospinal fluid (CSF), which bathes and nourishes the brain and spinal cord. Common symptoms can include nausea, vomiting, headache that is worse in the morning, and a reduced level of consciousness that causes drowsiness. Tumors causing focal compression on or irritation of the brain usually result in loss of neurologic function. This progressive loss of neurologic function can manifest as tinnitus (ringing in the ears) or aphasia (language problems).

Technical advancement has made surgical removal of brain tumors more effective and safer. Surgical management of intracranial tumors focuses on diagnosis and reduction of tumor mass. Depending on tumor location and patient health status, the neurosurgeon may perform a needle biopsy (called image-directed stereotactic needle biopsy) or a craniotomy to extract a piece of tumor for pathologic analysis. If the tumor is located in an area where surgery can be performed, the neurosurgeon generally will remove the mass if the patient can tolerate **general anesthesia**. Exceptions to a surgical option may be exercised to treat malignant tumors that are very sensitive to chemotherapy or radiation therapy (i.e., to manage lymphoma or germinoma). One of the most common types of tumors is the glioma, which accounts for 50% of all primary brain tumors.

### *Degenerative disorders of the spine*

Degenerative disorders of the spine are a common problem. Between 50% and 90% of the population will experience back pain at some point in their lifetime. Most of these symptoms subside on their own within a few weeks; the cost, however, is realized in decreased productivity and lost wages—a public health problem. Pain in the lumbar spine is the most common reason adults seek medical attention. The lumbar spine comprises five lumbar vertebra and supports the weight of the entire vertebral column and head. Lower back disorders are among the most frequent reasons for referral to a neurosurgeon. Lumbar discs are prone to herniation and desiccation (drying out) as a result of the heavy load they bear and the motion to which they are subject. Nerves that run from the vertebrae extend out to distant body parts, and degeneration of the discs may change bony structures in such a manner that can cause nerve compression. Typically, patients with degenerative disorders of the spine may experience pain, numbness, paresthesia (tingling), and restriction of neck movement (if the affected vertebra is in the cervical spine, which is located in the back of the neck).

### *Surgery for congenital abnormalities*

Congenital abnormalities arise during embryonic development. Important changes in growth and chemistry occur during the second week of human gestation; these changes contribute to the development of the nervous system. Several different types of cells proliferate as they move together or separate into other structures according to an orchestrated, natural timeline. Defects can occur at different stages of development. Among the defects with which infants can be born include myelomeningoceles, encephaloceles, hydrocephalus, and craniosynostosis.

### *Central nervous system infections*

Solitary or multiple brain abscesses can occur as a result of infection in the brain. Patients present with clinical symptoms such as focal (a specific area is affected) neurologic signs, seizures, altered mental status, and increased intracranial pressure. CT scans and **magnetic resonance imaging** (MRI) are helpful for identification of brain abscesses. Surgery is usually indicated if the abscess fails to resolve or worsens following antibiotic treatment, or if there are signs of mass effect and brain herniation. Although rare, a spinal epidural abscess can occur. Typically, bacteria can spread in patients who have acute bacterial meningitis (infection of the subarachnoid spaces and meninges). The specific type of bacteria varies according to the patient's age.

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

A neurosurgeon performs the procedure in a major hospital. The neurosurgeon is a medical doctor who has obtained two years of general surgery training, plus an additional five years of training in neurosurgery.

### *Functional neurosurgery*

Functional neurosurgery is a special type of surgical procedure used to manage movement disorder, epilepsy, and pain. Stereotactic neurosurgery makes use of a coordinate system that provides accurate navigation to a specific point or region in the brain. This is usually done by placing and fixing into position a frame on the scalp (using four threaded pins that penetrate the outer skull to stabilize the frame in position) under **local anesthesia**. A special box and stereotactic arc are placed to precisely determine X, Y, and Z coordinates of any point within the frame.

### *Epilepsy surgery*

Approximately 70 per 100,000 population in the United States takes antiepileptic medications for seizure disorders. The risk of developing epilepsy over a lifetime is 3%, and there are 100,000 new cases per year. The majority of cases (approximately 60,000) are epilepsy of the temporal lobe (the brain lobes located on the sides of the head). Approximately 25% of temporal lobe seizure patients who are prescribed antiepileptic drugs continue to have seizures that are not controlled or that can be controlled, but the side effects of the medication outweigh the therapeutic benefits. Approximately 5,000 new cases per year require epilepsy surgery (partial **anterior temporal lobectomy**). The patient and neurosurgeon should consider surgery if continued seizures cause injuries due to repeated falls; driving restrictions; limitation of social interactions; problems related to education and learning; and employment limitations.

### **The future of neurosurgery**

Neurosurgery as a field is faced with many new opportunities and challenges, based on advanced technological approaches and molecular approaches to neurosurgical problems. Advances in technology have allowed the neurosurgeon to precisely locate abnormal tissue in the brain and spinal cord, thereby preserving

## QUESTIONS TO ASK THE DOCTOR

- What the potential side effects that can arise as a result of surgery?
- How likely are complications to develop?
- How long will recovery take?
- Will I undergo rehabilitation, and if so, for how long?

normal tissues from surgical trauma. In addition to cardiovascular neurosurgery, functional neurosurgery, neuro-oncologic neurosurgery (surgical removal of brain tumors), and spinal surgery, the future holds many new research innovations. In the new millennium, the field of molecular neurosurgery can make it possible to introduce genetic material into nerve cells and to redirect protein synthesis—to work toward reversing the disease process, in general.

## Nonsteroidal anti-inflammatory drugs

### Definition

Nonsteroidal anti-inflammatory drugs (NSAIDs) are medications other than **corticosteroids** that relieve pain, swelling, stiffness, fever, and inflammation. The most commonly used NSAIDs, including **aspirin**, ibuprofen, and naproxen, are available as over-the-counter (OTC) preparations; most, however, are prescription drugs. The use of NSAIDs for inflammation and low-grade pain is steadily increasing; in the early 2000s, these drugs accounted for 70 million prescriptions and 30 billion OTC purchases every year in the United States alone. They are one of the oldest classes of pain relievers, aspirin having been introduced for human use in 1829. One important reason why NSAIDs are so widely prescribed and recommended is that they have a very low rate of addiction.

### Purpose

Nonsteroidal anti-inflammatory drugs are prescribed for a variety of painful conditions, including arthritis, bursitis, tendinitis, gout, menstrual cramps, sprains, strains, and other injuries. They may be used for treatment of postsurgical pain that is either too mild to require narcotic **analgesics** or follows a period of use of stronger analgesics. Ketorolac (Toradol) may be used in place of narcotics for treatment of acute pain in patients who should not receive narcotics.

### Description

The nonsteroidal anti-inflammatory drugs are a group of agents that inhibit prostaglandin synthetase, thereby reducing the process of inflammation. As a group, they are all effective analgesics. Some, including the salicylates, ibuprofen, and naproxen, are also useful antipyretics (fever-reducers).

Although NSAIDs fall into discrete chemical classes, they are usually divided into the nonselective NSAIDs and the COX-2 specific agents. Among the nonspecific NSAIDs are diclofenac (Voltaren), etodolac (Lodine), flurbiprofen (Ansaid), ibuprofen (Motrin, Advil, Rufen), ketoprofen (Orudis), ketorolac (Toradol), nabumetone (Relafen), naproxen (Naprosyn), naproxen sodium (Aleve, Anaprox, Naprelan), and oxaprozin (Daypro). The only COX-2 specific drug remaining on the market in the United States as of 2007 is celecoxib (Celebrex); four other drugs in this class were withdrawn in the United States in 2004 because of reports that they increased patients' risks

## KEY TERMS

**Ankylosing spondylitis**—An autoimmune disorder of the joints in the spinal column, usually marked by pain and stiffness in the lower part of the spine.

**Antipyretic**—A medication that lowers fever.

**Bursitis**—Inflammation of the tissue around a joint.

**Inflammation**—Pain, redness, swelling, and heat that usually develop in response to injury or illness.

**Metabolites**—The chemicals produced in the body after nutrients, drugs, enzymes or other materials have been changed (metabolized).

**Salicylates**—A group of drugs that includes aspirin and related compounds; used to relieve pain, reduce inflammation, and lower fever.

**Tendinitis**—Inflammation of a tendon a tough band of tissue that connects muscle to bone.

of heart attack and stroke, and a fifth in Australia in 2007 because of reports of increased risk of liver failure.

Nonselective NSAIDs inhibit both cyclooxygenase 1 and cyclooxygenase 2 (COX-2). Cyclooxygenase 1 is important for such body processes as platelet aggregation, the regulation of blood flow in the kidney and stomach, and the regulation of gastric acid secretion. The inhibition of cyclooxygenase 1 is considered the primary cause of NSAID toxicity, including gastric ulceration and bleeding disorders. COX-2 is the primary cause of pain and inflammation. Celecoxib is a relatively selective COX-2 agent; it may cause the same adverse effects as the nonselective drugs, although with somewhat reduced frequency.

The analgesic activity of NSAIDs has not been fully explained. Antipyretic activity may be caused by the inhibition of prostaglandin E2 (PGE2) synthesis.

Although not all NSAIDs have approved indications for all uses, as a class, they are used for:

- ankylosing spondylitis
- bursitis
- dental pain
- fever
- gout
- headache
- juvenile arthritis
- pain from metastatic bone cancer
- mild-to-moderate postoperative pain
- osteoarthritis

- premenstrual syndrome (PMS)
- primary dysmenorrhea (painful menstrual periods)
- renal colic
- rheumatoid arthritis
- tendinitis

As of the early 2000s, NSAIDs have been studied for their potential effectiveness in lowering the risk of certain types of cancer, particularly colon, prostate, and ovarian cancers. More research needs to be done, however, to confirm the drugs' ability to protect against cancer.

### Recommended dosage

Recommended doses vary, depending on the patient, the type of nonsteroidal anti-inflammatory drug prescribed, the condition for which the drug is prescribed, and the form in which it is used. The patient is advised to consult specific sources for detailed information or ask a physician.

### Precautions

The most common hazard associated with NSAID use is gastrointestinal intolerance and ulceration. This may occur without warning and is a greater risk among patients over the age of 65. The risk appears to rise with increasing length of treatment and increasing dose. Patients should be aware of the warning signs of gastrointestinal (GI) bleeding.

Allergic reactions are rare, but may be severe. Patients who have allergic reactions to aspirin should not be treated with NSAIDs.

Because NSAID metabolites are eliminated by the kidney, renal toxicity should be considered. Clinicians should monitor kidney function before and during NSAID use.

Among the NSAIDs that are classed as pregnancy category B are ketoprofen, naproxen, naproxen sodium, flurbiprofen, and diclofenac. Category C NSAIDs include Etodolac, ketorolac, mefenamic acid, meloxicam, nabumetone, oxaprozin, tolmetin, piroxicam, and celecoxib. Breastfeeding is not advised while taking NSAIDs.

Many other rare but potentially serious adverse effects have been reported with NSAIDs. The consumer should consult specific references.

### Interactions

Many drug interactions have been reported with NSAID therapy. The most serious are those that may affect the bleeding hazards associated with NSAIDs. Consumers are advised to consult specific references

for further information. A partial list of interacting drugs includes:

- blood-thinning drugs such as warfarin (Coumadin)
- other nonsteroidal anti-inflammatory drugs
- heparin
- tetracycline antibiotics
- cyclosporine
- digitalis drugs
- lithium
- methotrexate
- phenytoin (Dilantin)
- zidovudine (AZT, Retrovir)

## Nursing homes

### Definition

A nursing home is a long-term care facility licensed by the state that offers 24-hour room and board and health care services, including basic and skilled nursing care, rehabilitation, and a full range of other therapies, treatments, and programs. Other names for nursing homes are skilled nursing facilities (SNFs) and skilled nursing units (SNUs). There were about 16,100 nursing homes in the United States as of 2005. People who live in nursing homes are referred to as residents.

### Description

Slightly over 5% of people 65 years and older occupy nursing homes, congregate housing, assisted living communities, and board-and-care homes. At any given time, approximately 4% of the population of the United States is in nursing homes with the rate of nursing home use increasing with age from 1.4% of the young-old to 24.5% of the oldest-old. Some SNFs accept younger adults (anyone over the age of 18) who need physical or occupational therapy following an

(Jim West/Alamy)

accident or illness. Nearly 50% of those 95 years old and older live in nursing homes. Nursing homes must meet the physical, emotional, and social needs of its residents.

### Required care plans

There are federal laws regarding the care given in a nursing home, and it is essential that staff members become aware of these regulations. Staff members are required to conduct a thorough assessment of each new resident during the first two weeks following admission. The assessment includes the resident's ability to move, his or her rehabilitation needs, the status of the skin, any medical conditions that are present, nutritional state, and abilities regarding activities of daily living.

In some cases, the nursing home residents are unable to communicate their needs to the staff. Therefore, it is particularly important for nurses and other professionals to look for problems during their assessments. Signs of malnutrition and dehydration are especially important when assessing nursing home residents.

It is not normal for an elderly person to lose weight. However, some people lose their ability to taste and smell as they age and may lose interest in food. This can result in malnutrition, which can lead to confusion and impaired ability to fight off disease.

Older people are also more susceptible to dehydration. Their medications may lead to dehydration as a side effect, or they may limit fluids because they are too afraid of uncontrolled urination. It is very dangerous to be without adequate fluid, so the nurse and other staff must be able to recognize early signs of dehydration.

When the assessment is complete, a care plan is developed. This plan is subject to change as changes in the resident's condition occur.

Nursing homes are often the only alternative for patients who require nursing care over an extended period of time. Such persons are too ill to remain at home, with families, or in less structured long-term facilities. These individuals are unable to live independently and need assistance with activities of daily living (ADLs). Some nursing homes offer specialized care for certain medical conditions such as Alzheimer's disease.

Commonly, nursing home residents are no longer able to participate in the activities they once enjoyed. However, it is required by law that these facilities help residents achieve their highest possible quality of life.

## KEY TERMS

**Activities of daily living (ADLs)**—Self-care activities performed during the course of a normal day such as eating, bathing, dressing, toileting, etc.

**Assisted living**—A type of facility for people who are not able to live independently but do not require the level of skilled nursing provided by a nursing home.

**Congregate housing**—A type of housing arrangement for seniors that offers independent living in separate apartments as well as opportunities to share activities of daily living with other residents. Congregate housing does not usually involve assisted living or skilled nursing care, however.

**Culture change**—A term that refers to a movement in the United States to make nursing homes more resident-centered and less like hospitals.

**Long-term care**—Residential care over a period of time. A nursing home is a type of long-term care facility that offers nursing care and assistance with daily living tasks.

**Medicaid**—The federally funded program in the United States for state-operated programs that provide medical assistance to permanently disabled patients and to low-income people. Medicaid is the medical assistance provided in Title XIX of the Social Security Act.

**Medicare**—The federally-funded national health insurance program, provided for by Title XVIII of the Social Security Act in the United States for all people over the age of 65.

**Restraint**—A physical device or a medication designed to restrict a person's movement.

**Skilled nursing facility (SNF)**—Another name for a nursing home.

It is important for residents to have as much control as possible over their everyday lives. Laws and regulations exist to raise nursing home quality of life and care standards.

By law, nursing homes cannot use chemical or physical restraints unless they are essential for treating a medical problem. There are many dangers associated with the use of restraints, including the chance of a fall if a resident tries to walk while restrained. The devices may also lead to depression and decreased self-esteem. A doctor's order is necessary before restraints can be used in a nursing home.

## Licensing

The Joint Commission (formerly the Joint Commission on the Accreditation of Health Care Organizations) offers accreditation to nursing homes through the Long Term Care Accreditation Program established in 1966. This group helps nursing homes improve their quality of care. The commission periodically surveys nursing homes to check on quality issues.

A nursing home may be certified by **Medicare** or **Medicaid** if it meets the criteria of these organizations; 98.5% of nursing homes in the United States were certified to participate in one or both programs as of 2005. Families should be informed of the certifications a nursing home holds. Medicare and Medicaid are the main sources of financial income for nursing homes in the United States.

The state in which a nursing home is located conducts inspections every nine to 15 months. Fines and other penalties may be enforced if the inspection reveals areas where the nursing home does not meet requirements set by that state and the federal government. Problem areas are noted in terms of scope and severity. The scope of a problem is how widespread it is, and the severity is the seriousness of its impact on the residents. When a nursing home receives an inspection report, it must post it in a place where it can be easily seen by residents and their guests.

## Contract

When a resident checks into a nursing home, a contract is drawn up between the patient and the facility. This document includes information regarding the rights of the residents. It also provides details regarding services provided and discharge policies.

## Resident decision-making

Decisions are made by each nursing home resident unless he or she has signed an advanced directive giving this authority to someone else. In order for health care decisions to be made by another person, the resident must have signed a document called a durable **power of attorney** for health care.

## Costs

Nursing **home care** is costly. The rate normally includes room and board, housekeeping, bedding, nursing care, activities, and some personal items. Additional fees may be charged for haircuts, telephones, and other personal items.

Medicare covers the cost of some nursing home services, such as skilled nursing or rehabilitative care.

This payment may be activated when the nursing home care is provided after a Medicare qualifying stay in the hospital for at least three days. It is common for nursing homes to have only a few beds available for Medicare or Medicaid residents. Residents relying solely on these types of coverage must wait for a Medicare or Medicaid bed to become available.

Medicare supplemental insurance, such as Medigap, assists with the payment of nursing home expenses that are not covered by Medicare.

Medicaid qualifications vary in each state. Families of potential residents should check with their state government to determine coverage options. According to a federal law, a nursing home that drops out of the Medicaid program cannot evict current residents whose care is supported by Medicaid.

Private insurance, such as long-term insurance, may cover costs associated with a nursing home. People may enroll in these plans through their employers or other group insurance policies.

In many cases, nursing homes are paid for by the residents' personal funds. When these funds are exhausted, the residents sometimes become eligible for Medicaid assistance.

### *Patients' rights*

It is important for the professionals working in nursing homes to be aware of the residents' rights. Residents are informed of their rights when they are admitted. Residents have the right to:

- manage their finances
- privacy (for themselves and their belongings)
- make decisions (unless advanced directives or durable power of attorney exist)
- see visitors in private
- receive information regarding their medical care and treatments
- have social services
- leave the nursing home after giving the required amount of notice (A stay in a nursing home is normally considered voluntary; however, the facility will consider a variety of factors before discharging a resident. These factors include the resident's health, safety, and potential danger to self or others, as well as the resident's payment for services. The contract will state how much notice is required before a resident may transfer to another facility, return home, or move in with a family member.)

### *Family involvement*

In some cases, a nursing home is chosen after the family has only a short time to prepare for the change. For example, when a patient is unable to care for himself or herself due to a sudden illness or injury, the family must turn to nursing home care without having the luxury of researching this option over time. The nursing home's costs must be explained to the resident or family prior to admission. It is important for the nursing home staff to be willing to answer the family's questions and reassure them about the care their loved one will receive. To help with choosing a nursing home, Medicare has set up a Nursing Home Compare website at <http://www.medicare.gov/NHCompare/> that allows users to search by geography, proximity, the name of the nursing home, or special focus.

Nursing home professionals have an opportunity to continue to work closely with the resident's family and loved ones over the course of a resident's stay. In these facilities, concerned family members and friends of the resident are involved in his or her care, and may have guardianship or other decision-making responsibility. These individuals may voice their concerns through meetings between staff and family members. Those with legal guardianship are entitled to see a resident's medical records, care plans, and other related material.

### *Communication*

As in other health care settings, communication among nursing home staff is very important. In nursing homes, the care is based on a team approach. Physicians, nurses, and allied health professionals work together to make sure the resident is able to experience the highest quality of life possible.

In many cases, physicians who have had a long-term relationship with a patient continue treatment after the patient has been admitted to a nursing home. It is important for the nursing home staff to leave blocks of time open in the schedule for physician visits. It is also the staff's duty to keep the personal physicians apprised of a resident's medical condition.

The resident, physician, and resident's legal guardian and family must be told immediately if any of the following situations arise: an accident involving the resident, the need for a major treatment change, and a decision regarding discharge or transfer. Unless an emergency arises, the nursing home must give 30 days written notice of discharge or transfer. The family may appeal the decision.

### Culture change

Culture change refers to a movement to transform nursing homes into more homelike and less hospital-like communities. Spearheaded by groups like LIFESPAN, the Eden Alternative, and the Green House Project, people involved in changing nursing homes formed the Pioneer Network in 2000. The network advocates giving elders as much choice and self-determination as possible, including more opportunities for human companionship and keeping pets. As of 2004, nine states (Colorado, Florida, Illinois, Michigan, New Jersey, North Carolina, Pennsylvania, South Carolina, and Washington) had formed culture change coalitions.

The Pioneer Network drew up a list of values and principles that has been adopted by the NCCNHR (formerly the National Citizens' Coalition for Nursing Home Reform and other groups:

- Know each person.
- Each person can and does make a difference.
- Relationship is the fundamental building block of a transformed culture.
- Respond to spirit, as well as mind and body.
- Risk taking is a normal part of life.
- Put person before task.
- All elders are entitled to self-determination wherever they live.
- Community is the antidote to institutionalization.
- Do unto others as you would have them do unto you—yes, the Golden Rule.
- Promote the growth and development of all.
- Shape and use the potential of the environment in all its aspects: physical, organizational, psycho/social/spiritual.
- Practice self-examination, searching for new creativity and opportunities for doing better.
- Recognize that culture change and transformation are not destinations but a journey, always a work in progress.

### Results

The quality of care in nursing homes is an important issue. Quality issues include:

- Ratios of staff to patients. Advocacy groups are pushing for increased staff-to-patient ratios in nursing homes.) The NCCNHR recommends one direct care staff member (R.N., L.V.N., or C.N.A.) per five residents during the day shift, per 10 residents during the evening shift, and per 15 residents during the night shift.
- Elder abuse. It is important for nursing home personnel to look for signs of abuse or neglect when a

### WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

The nursing home staff may include an administrator, medical director, director of nursing, and directors for other allied health services. It is important for nursing home staff to understand the policies regarding care in these types of facilities.

The following professionals may provide care and treatments in nursing homes:

- physicians, including psychiatrists
- nurses
- nursing assistants
- dietitians
- physical, occupational, and speech therapists
- pharmacists
- social activities staff
- dentists
- social workers or psychological counselors
- chaplains
- such other staff as custodians and office personnel

resident checks in and during a resident's stay. Signs of abuse include bodily injuries that appear suspicious, visible harm to the wrist or ankles that may indicate the use of restraints, skin ulcers that seem neglected, poor hygiene, inadequate nutrition, unexplained dehydration, untreated medical problems, or such personality disorders as excessive nervousness or withdrawal. The nurse or allied health professional is to report any signs of abuse to the supervisor or physician.

- Reimbursement. Nursing home administrators report that reimbursements do not cover the expenses, while nursing home advocates would like a higher portion of revenues to be allocated for direct patient care.

## Obstetric and gynecologic surgery

### Definition

Obstetric and gynecologic surgery refers to procedures that are performed to treat a variety of conditions affecting the female reproductive organs. The main structures of the reproductive system are the vagina, the uterus, the ovaries, and the fallopian tubes.

### Description

Obstetrics is the branch of medicine that focuses on women during pregnancy, childbirth, and the postpartum period. Gynecology is a broader field, focusing on the general health care of women and treating conditions that affect the female reproductive organs. Medical doctors who choose to specialize in obstetrics and gynecology must undergo at least four years of post-medical school training (called a residency) in the areas of women's general health, pregnancy, labor and delivery, preconceptional and postpartum care, prenatal testing, and genetics. Obstetrician-gynecologists (also called OB-GYNs) may also subspecialize in the areas of gynecologic oncology (the treatment of cancers that affect the reproductive system), maternal-fetal medicine (the care of high-risk pregnancies), reproductive endocrinology and infertility (the study and treatment of the reproductive glands and hormones and the causes of infertility), and urogynecology (treatment of urinary tract and pelvic disorders).

### *Surgical procedures*

There are a wide range of surgical procedures that have been developed to treat the various conditions that affect the female reproductive organs.

**THE VAGINA.** The vagina is the muscular canal that extends from the opening of the vulva (the external female genitals) to the cervix, the lower part of the

uterus. The vagina is the outlet for menstrual blood and is also where the penis is inserted during sexual intercourse.

Some common surgical procedures that are performed on the vagina include:

- **Episiotomy.** A surgical incision made in the perineum (the area between the vagina and anus) to expand the opening of the vagina to prevent tearing during delivery.
- **Colporrhaphy.** Surgical repair of the vagina may be necessary after childbirth, sexual assault, or other injuries.
- **Colpotomy.** This incision into the wall of the vagina may be used to excise ovarian cysts, perform tubal ligation, or remove uterine fibroids.
- **Egg Retrieval.** This is a procedure used to extract the eggs from the ovaries prior to in vitro fertilization. A needle is placed through the vaginal wall to extract the eggs from the ovaries under ultrasound guidance.
- **Colposcopy.** A colposcope is a specialized instrument used to visualize the vagina and cervix, to diagnose abnormalities, or to test for the presence of precancerous or cancerous cells.

**THE UTERUS.** The uterus is the hollow, muscular organ at the top of the vagina. The cervix is the neck-shaped opening at the lower part of the uterus, while the fundus is the rounded upper portion. The endometrium is the inner lining of the uterus; it is where a fertilized egg will implant during the early days of pregnancy. The endometrium normally sheds during each menstrual cycle if the egg released during ovulation has not been fertilized. The myometrium is the middle muscular layer of the uterus; it is the myometrium that rhythmically contracts during labor contractions.

Some common surgical procedures that are performed on the uterus include:

## KEY TERMS

**Ectopic pregnancy**—A pregnancy that occurs outside of the uterus, most often in the fallopian tubes.

**Endometriosis**—A condition in which the endometrium (lining of the uterus) grows outside of the uterus.

**Ovarian cysts**—Fluid-filled cavities on the surface of the ovary that may cause pain and bleeding if they become too large.

**Uterine fibroids**—Also called leiomyomas; benign growths in the smooth muscle of the uterus.

**Uterine prolapse**—A condition which the uterus descends into or beyond the vagina.

- **Myomectomy.** A procedure in which myomas (uterine fibroids) are surgically removed from the uterus.
- **Cesarean section.** A surgical procedure in which incisions are made through the woman's abdomen and uterus to deliver her baby.
- **Cervical cerclage.** The cervix is stitched closed to prevent a miscarriage or premature birth.
- **Cervical cryosurgery.** Cryosurgery freezes and destroys an area of the cervix in which precancerous cells have been found.
- **Induced abortion.** The intentional termination of a pregnancy before the fetus can live independently.
- **Hysterectomy.** The removal of part or all of the uterus may be done to treat uterine cancer, fibroid tumors, endometriosis, uterine prolapse, or other conditions of the uterus.
- **Hysterotomy.** This incision into the uterus is done during a cesarean section, open fetal surgery, and some second-trimester abortions.
- **Dilatation and curettage.** D&C is a gynecological procedure in which the cervix is dilated (expanded) and the lining of the uterus (endometrium) is scraped away.

**THE OVARIES.** The ovaries are egg-shaped structures located to each side of the uterus. It is within the ovaries that the female egg develops. A mature egg is released from one of the ovaries approximately every 28 days during a process called ovulation.

The surgical procedures that are performed on the ovaries include:

- **Oophorectomy.** One or both ovaries may be removed during this procedure to prevent or treat ovarian or other cancers, to remove large ovarian cysts, or to treat endometriosis.

- **Cystectomy.** An ovarian cystectomy may be used to remove part of an ovary to treat ovarian tumors or cysts.

**THE FALLOPIAN TUBES.** The fallopian tubes are the structures that carry a mature egg from the ovaries to the uterus. These tubes, which are about 4 in (10 cm) long and 0.2 in (0.5 cm) in diameter, are found on the upper outer sides of the uterus, and open into the uterus through small channels. It is within a fallopian tube that fertilization, the joining of the egg and the sperm, takes place.

Some common surgical procedures that are performed on the fallopian tubes include:

- **Salpingostomy.** An incision is made in the fallopian tube, often to excise an ectopic pregnancy.
- **Salpingectomy.** One or both fallopian tubes are removed in this procedure. It may be used to treat ruptured or bleeding fallopian tubes (as a result of ectopic pregnancy), infection, or cancer.
- **Tubal ligation.** A permanent form of birth control in which a woman's fallopian tubes are surgically cut or blocked off to prevent pregnancy.

**THE VULVA.** The external female genital organs (or vulva) include the labia majora, two lips or folds that enclose the labia minora. The labia minora, in turn, are two lips or folds that enclose the clitoris, a small sensitive organ with a high number of nerve endings.

Some examples of surgeries that affect the vulva are:

- **Vulvectomy.** The vulva may be partially or completely removed, as in the case of vulvar cancer.
- **Laceration or hematoma repair.** Vulvar hematoma (a localized collection of blood) or laceration may result from a "straddle" injury, sexual assault, or childbirth. Severe hematomas may need surgical drainage.

### *Obstetric and gynecologic anesthesia*

There are a number of options available to women for pain relief during obstetric or gynecologic surgery. Pain medications given intravenously (into a vein) or intramuscularly (into a muscle) help to decrease the amount of pain during childbirth or certain procedures, although they will generally not completely eliminate pain.

Regional anesthesia, either a spinal or an epidural, is the preferred method of pain relief during childbirth and certain surgical procedures such as cesarean section, tubal ligation, **cervical cerclage**, and others that do not require the patient to be unconscious. The benefits of regional anesthesia include allowing the patient to be awake during the surgery, avoiding the risks of **general anesthesia**, and allowing early

contact between mother and child in the case of a cesarean section. Spinal anesthesia involves inserting a needle into a region between the vertebrae of the lower back and injecting numbing medications. An epidural is similar to a spinal except that a catheter is inserted so that numbing medications may be administered as needed. Some women experience a drop in blood pressure when a regional anesthetic is administered; this can be countered with fluids and/or medications.

In some instances, use of general anesthesia may be indicated. General anesthesia can be more rapidly administered in the case of an emergency (e.g. severe fetal distress). If the mother has a coagulation disorder that would be complicated by a drop in blood pressure (a risk with regional anesthesia), general anesthesia is an alternative. General anesthesia is also used for some of the more complicated and prolonged obstetric and gynecologic surgeries.

# Omphalocele repair

## Definition

An omphalocele is a congenital defect in which internal organs such as the liver, stomach, and intestines, are on the outside of the abdomen, at the umbilical cord, instead of being located inside the body. These abdominal cavity contents are enclosed in a thin, transparent, membranous sac that is actually formed inside the umbilical cord tissue. An omphalocele repair is a surgical procedure in which the organs are returned to the inside of the body, and the opening in the abdominal wall is closed. Whenever possible, a normal-looking belly button is created.

## Purpose

The internal organs need to be enclosed inside the abdomen for protection against injury, and to ensure that the tissue remains properly hydrated. The omphalocele repair is necessary to return the tissue to the inside of the body.

## Demographics

Omphaloceles usually occur in full-term infants, more frequently in boys than in girls. A recent study found that the ratio is two girls to three boys.

The presence of an omphalocele often occurs with other birth defects, including:

- heart defects, such as the tetralogy of Fallot
- imperforate anus, a malformation of the anorectal area of the gastrointestinal system
- urinary problems
- genetic disorders
- Beckwith-Wiedemann syndrome, with enlarged tongue, gigantism, and enlarged internal organs
- pentalogy of Cantrell, with malformations in the chest and abdominal area, including heart defects, and high mortality rate

To check for other congenital defects, x rays are usually taken of the heart, lungs, and diaphragm once the infant's condition has been stabilized after birth.

## Description

An omphalocele is a defect that can be viewed on sonogram during an **ultrasound** performed while the mother is pregnant. At about six to eight weeks of fetal development, the abdominal contents come out of the fetus's abdomen at the base of the umbilical cord. They return to the inside as development continues.

## KEY TERMS

**Congenital**—Present at the time of birth.

**Edema**—Swelling, or filling with fluid.

**Gigantism**—A condition in which the individual grows to an abnormally large size. Mental development may or may not be normal.

**Intravenous**—The use of a special tube, or catheter, inserted into a vein. Through the catheter, the infant may receive medications, as well as feedings, until taking food directly into the stomach is possible.

**Sonogram**—Image, or picture, obtained when using a machine called an ultrasound to look inside the uterus when the mother is pregnant. It is a painless procedure that sends out sound waves to the baby, and as the sound waves bounce off the object the baby an image is created on a monitor.

If this process is interrupted in some way during the seventh to tenth week of fetal development, the contents remain on the outside, and an omphalocele develops. Because the abdominal contents are now on the outside of the body, the inside cavity may not develop properly. For this reason, a large omphalocele cannot simply be placed back inside because the cavity may be too small. The internal organs will need to be protected and kept hydrated while the inside is gradually stretched. Small amounts of the omphalocele are returned at any one time to allow the cavity to gradually stretch to accommodate them. If the sac surrounding the tissue has ruptured, or broken, there is a greater risk of infection, tissue damage, loss of **body temperature**, and dehydration.

The repair may be performed in stages. If the omphalocele is very small, it may be possible to return all of the contents to the inside, and surgically close the opening. If the omphalocele is too large to do this all at once, some contents will remain on the outside while a sterile pouch is created to protect the tissue that remains on the outside. To be sure that the tissue does not dry out, it will be covered with warm and moist sterile **dressings**. The infant can lose considerable body heat through the large amount of exposed surface area, so keeping him or her warm, and closely monitoring body temperature is a high priority. An antibacterial solution may be used to decrease the risk of infection. The infant will have a tube that goes in through the nose or mouth and down into the stomach, called a nasogastric tube. Suction is used to keep the stomach empty, avoiding the chance of vomiting,

or of the fluid moving from the stomach up into the lungs. The contents of the sac will be carefully examined to make sure that none of the tissue is damaged or dead, and to check for signs of intestinal birth defects before being inserted into the body.

The omphalocele repair is a surgical procedure performed under **general anesthesia**. The infant will receive medication to relax his or her muscles, and to help the surgery move forward without causing any pain. A large omphalocele repair may be done in stages over several weeks. The contents of the sac are often swollen, which makes it impossible to return them into the small cavity all at once. The return of the sac contents into the abdominal cavity creates intra-abdominal pressure, which may cause the infant to have difficulty breathing. To help the infant breathe, a special breathing tube may be inserted. The tube is attached to a machine that regulates the length and frequency of the breaths. When the necessary surgeries have been completed, the suturing will be done in such a way as to leave, if possible, a somewhat normal-looking belly button. A large omphalocele repair can leave a large, unsightly scar. For cosmetic purposes, the scar may be operated on at a later date to make it less noticeable. Gastroesophageal reflux, which may require additional surgery, is common in patients with a repaired omphalocele.

## Diagnosis/Preparation

The diagnosis of an omphalocele may take place during an ultrasound while the mother is still pregnant. A recent study found that 75% of omphaloceles were diagnosed by ultrasound, most commonly around week 18 of pregnancy. To avoid any injury to the omphalocele sac, a cesarean birth may be performed so that the infant does not travel through the birth canal. If the omphalocele has not been detected prior to birth, it is immediately noticeable upon birth.

## Aftercare

The infant will need to spend some time after the surgery in the **intensive care unit**. Because infants are unable to properly regulate their temperature, they are placed in special beds that are kept warm. They will usually need oxygen and a breathing tube to help them breathe for a while. The breathing machine is referred to as **mechanical ventilation**, or a ventilator. This machine helps the baby breathe at the right depth and frequency for his or her age, allowing the infant to conserve energy for other functions. An infant that is struggling for air spends much energy on breathing, which slows the healing process.

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

This procedure is performed by a surgeon, preferably board certified, who specializes in pediatric surgery and has experience with such conditions. The repair needs to be done in a hospital, preferably one with a neonatal intensive care unit, with specially-trained pediatric intensive care nurses and staff.

Once the bowels are moving normally, feedings will be slowly started. Feedings are usually first done through a nasogastric tube so the infant does not need to use energy for sucking and swallowing. Sucking on a pacifier is avoided because this could cause the bowel to expand with air and slow down the healing process. Until the nasogastric tube is used, the infant will be fed intravenously. The intravenous line provides the infant with needed **antibiotics**, pain medication, and fluids.

Infants with an omphalocele may spend quite some time, perhaps several months, in the hospital before being discharged home. It may take them some time to learn to feed through normal infant sucking and swallowing. Their development may be delayed, and they may require help for months as they catch up to the physical and mental development that is normal for their age. If the parents do not live near the hospital, they should be encouraged to spend as much time with their infant as possible to ensure infant-parent bonding. When the repair is done in stages, it can be difficult for the parents to remain patient. The birth of a child with a birth defect can be quite emotionally difficult for the parents. Individuals trained to assist parents through this time should meet with them to provide information and support.

## Risks

All surgery has risks, from the procedure itself as well as the anesthesia. Infection and bleeding are the two primary risks of surgery. Breathing problems and reactions to the anesthetics are the main risks from anesthesia. In addition to these standard surgical risks, an omphalocele repair has the associated risks of damage to the organs on the outside of the body, additional breathing problems from the added pressure inside the abdominal cavity when the contents are returned, infection of the abdominal cavity (peritonitis), and a slowing or paralysis of the bowels (paralytic ileus).

## QUESTIONS TO ASK THE DOCTOR

- In addition to the omphalocele, what other medical conditions does the child have?
- What is the chance of surviving the procedures needed to correct these problems?
- What quality of life can the child have if all the procedures are successfully performed?
- How many of these procedures has the surgeon performed?
- What outcomes has the surgeon's patients had?
- How long will the child need to stay in the hospital?
- What about breastfeeding?
- What is the likelihood of a similar condition being present in future children for this couple?

## Normal results

The expected results depend on many factors, including:

- size of the omphalocele
- degree of development of the abdominal cavity
- presence and extent of other congenital defects
- damage to or loss of intestinal tissue
- whether the infant was full-term or premature at birth

Many omphaloceles can be completely corrected with excellent results.

## Morbidity and mortality rates

An omphalocele occurs in about one in 5,000 live births. Other congenital defects are common. In one recent study, 50% of infants with omphalocele had other birth defects, primarily heart-related. On average, the infants spent three days on a ventilator, with about 45 total days spent in the hospital. The mortality rate was 8%, mostly due to heart problems.

## Alternatives

There are no non-surgical alternatives to omphalocele repair. The abdominal contents need to be returned to the abdominal cavity, and the opening closed. While awaiting surgical repair, a sterile elastic bandage may be placed on the omphalocele to decrease edema (fluid accumulation).

## Oophorectomy

### Definition

Unilateral oophorectomy (also called an ovariectomy) is the surgical removal of an ovary. If one ovary is removed, a woman may continue to menstruate and have children. If both ovaries are removed, a procedure called a bilateral oophorectomy, menstruation stops and a woman loses the ability to have children.

### Purpose

Oophorectomy is performed to:

- remove cancerous ovaries
- remove the source of estrogen that stimulates some cancers
- remove a large ovarian cyst
- excise an abscess
- treat endometriosis

In an oophorectomy, one or a portion of one ovary may be removed or both ovaries may be removed. When an oophorectomy is done to treat ovarian cancer or other spreading cancers, both ovaries are removed (called a bilateral oophorectomy). Removal of the ovaries and fallopian tubes is performed in about one-third of hysterectomies (surgical removal of the uterus), often to reduce the risk of ovarian cancer.

Oophorectomies are sometimes performed on premenopausal women who have estrogen-sensitive breast cancer in an effort to remove the main source of estrogen from their bodies. This procedure has become less common than it was in the 1990s. Today, chemotherapy drugs are available that alter the production of estrogen and tamoxifen blocks any of the effects any remaining estrogen may have on cancer cells.

Until the 1980s, women over age 40 having hysterectomies routinely had healthy ovaries and fallopian tubes removed at the same time. This operation is called a bilateral **salpingo-oophorectomy**. Many physicians reasoned that a woman over 40 was approaching menopause and soon her ovaries would stop secreting estrogen and releasing eggs. Removing the ovaries would eliminate the risk of ovarian cancer and only accelerate menopause by a few years.

In the 1990s, the thinking about routine oophorectomy began to change. The risk of ovarian cancer in women who have no family history of the disease is less than 1%. Meanwhile, removing the ovaries increases the risk of cardiovascular disease and accelerates osteoporosis unless a woman takes prescribed hormone replacements.

Under certain circumstances, oophorectomy may still be the treatment of choice to prevent breast and

## KEY TERMS

**Cyst**—An abnormal sac containing fluid or semi-solid material.

**Endometriosis**—A benign condition that occurs when cells from the lining of the uterus begin growing outside the uterus.

**Fallopian tubes**—Slender tubes that carry ova from the ovaries to the uterus.

**Hysterectomy**—Surgical removal of the uterus.

**Osteoporosis**—The excessive loss of calcium from the bones, causing the bones to become fragile and break easily.

ovarian cancer in certain high-risk women. A study done at the University of Pennsylvania and released in 2000 showed that healthy women who carried the BRCA1 or BRCA2 genetic mutations that predisposed them to breast cancer had their risk of breast cancer drop from 80% to 19% when their ovaries were removed before age 40. Women between the ages of 40 and 50 showed less risk reduction, and there was no significant reduction of breast cancer risk in women over age 50. A 2002 study showed that five years after being identified as carrying BRCA1 or BRCA2 genetic mutations, 94% of women who had received a bilateral salpingo-oophorectomy were cancer-free, compared to 79% of women who had not received surgery.

The value of ovary removal in preventing both breast and ovarian cancer has been documented. However, there are disagreements within the medical community about when and at what age this treatment should be offered. Preventative oophorectomy, also called prophylactic oophorectomy, is not always covered by insurance. One study conducted in 2000 at the University of California at San Francisco found that only 20% of insurers paid for preventive bilateral oophorectomy (PBO). Another 25% had a policy against paying for the operation, and the remaining 55% said that they would decide about payment on an individual basis.

## Demographics

Overall, ovarian cancer accounts for only 4% of all cancers in women. But the lifetime risk for developing ovarian cancer in women who have mutations in BRCA1 is significantly increased over the general population and may cause an ovarian cancer risk of 30% by age 60. For women at increased risk,

oophorectomy may be considered after the age of 35 if childbearing is complete.

Other factors that increase a woman's risk of developing ovarian cancer include age (most ovarian cancers occur after menopause), the number of menstrual periods a woman has had (affected by age of onset, pregnancy, breastfeeding, and oral contraceptive use), history of breast cancer, diet, and family history. The incidence of ovarian cancer is highest among Native Americans (17.5 cases per 100,000 population), white (15.8 per 100,000), Vietnamese (13.8 per 100,000), white Hispanic (12.1 per 100,000), and Hawaiian (11.8 per 100,000) women; it is lowest among Korean (7.0 per 100,000) and Chinese (9.3 per 100,000) women. African American women have an ovarian cancer incidence of 10.2 per 100,000 population.

## Description

Oophorectomy is done under general or regional anesthesia. It is often performed through the same type of incision, either vertical or horizontal, as an abdominal **hysterectomy**. Horizontal incisions leave a less noticeable scar, but vertical incisions give the surgeon a better view of the abdominal cavity. After the incision is made, the abdominal muscles are stretched apart, not cut, so that the surgeon can see the ovaries. Then the ovaries, and often the fallopian tubes, are removed.

Oophorectomy can sometimes be done with a laparoscopic procedure. With this surgery, a tube containing a tiny lens and light source is inserted through a small incision in the navel. A camera can be attached that allows the surgeon to see the abdominal cavity on a video monitor. When the ovaries are detached, they are removed through a small incision at the top of the vagina. The ovaries can also be cut into smaller sections and removed.

The advantages of abdominal incision are that the ovaries can be removed even if a woman has many adhesions from previous surgery. The surgeon gets a good view of the abdominal cavity and can check the surrounding tissue for disease. A vertical abdominal incision is mandatory if cancer is suspected. The disadvantages are that bleeding is more likely to be a complication of this type of operation. The operation is more painful than a laparoscopic operation and the recovery period is longer. A woman can expect to be in the hospital two to five days and will need three to six weeks to return to normal activities.

## Diagnosis/Preparation

Before surgery, the doctor will order blood and urine tests, and any additional tests such as **ultrasound**

or x rays to help the surgeon visualize the woman's condition. The woman may also meet with the anesthesiologist to evaluate any special conditions that might affect the administration of anesthesia. A colon preparation may be done, if extensive surgery is anticipated.

On the evening before the operation, the woman should eat a light dinner, then take nothing by mouth, including water or other liquids, after midnight.

### Aftercare

After surgery a woman will feel discomfort. The degree of discomfort varies and is generally greatest with abdominal incisions, because the abdominal muscles must be stretched out of the way so that the surgeon can reach the ovaries. In order to minimize the risk of postoperative infection, **antibiotics** will be given.

When both ovaries are removed, women who do not have cancer are started on hormone replacement therapy to ease the symptoms of menopause that occur because estrogen produced by the ovaries is no longer present. If even part of one ovary remains, it will produce enough estrogen that a woman will continue to menstruate, unless her uterus was removed in a hysterectomy. To help offset the higher risks of heart and bone disease after loss of the ovaries, women should get plenty of **exercise**, maintain a low-fat diet, and ensure intake of calcium is adequate.

Return to normal activities takes anywhere from two to six weeks, depending on the type of surgery. When women have cancer, chemotherapy or radiation are often given in addition to surgery. Some women have emotional trauma following an oophorectomy, and can benefit from counseling and support groups.

### Risks

Oophorectomy is a relatively safe operation, although, like all major surgery, it does carry some risks. These include unanticipated reaction to anesthesia, internal bleeding, blood clots, accidental damage to other organs, and post-surgery infection.

Complications after an oophorectomy include changes in sex drive, hot flashes, and other symptoms of menopause if both ovaries are removed. Women who have both ovaries removed and who do not take estrogen replacement therapy run an increased risk for cardiovascular disease and osteoporosis. Women with a history of psychological and emotional problems before an oophorectomy are more likely to experience psychological difficulties after the operation.

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

Oophorectomies are usually performed in a hospital operating room by a gynecologist, a medical doctor who has completed specialized training in the areas of women's general health, pregnancy, labor and childbirth, prenatal testing, and genetics.

Complications may arise if the surgeon finds that cancer has spread to other places in the abdomen. If the cancer cannot be removed by surgery, it must be treated with chemotherapy and radiation.

### Normal results

If the surgery is successful, the ovaries will be removed without complication, and the underlying problem resolved. In the case of cancer, all the cancer will be removed. A woman will become infertile following a bilateral oophorectomy.

### Morbidity and mortality rates

Studies have shown that the complication rate following oophorectomy is essentially the same as that following hysterectomy. The rate of complications associated with hysterectomy differs by the procedure performed. Abdominal hysterectomy is associated with a higher rate of complications (9.3%), while the overall complication rate for vaginal hysterectomy is 5.3%, and 3.6% for laparoscopic vaginal hysterectomy. The risk of **death** is about one in every 1,000 women having a hysterectomy. The rates of some of the more commonly reported complications are:

- excessive bleeding (hemorrhaging): 1.8–3.4%
- fever or infection: 0.8–4.0%
- accidental injury to another organ or structure: 1.5–1.8%

Because of the cessation of hormone production that occurs with a bilateral oophorectomy, women who lose both ovaries also prematurely lose the protection these hormones provide against heart disease and osteoporosis. Women who have undergone bilateral oophorectomy are seven times more likely to develop coronary heart disease and much more likely to develop bone problems at an early age than are premenopausal women whose ovaries are intact.

## QUESTIONS TO ASK THE DOCTOR

- Why is a oophorectomy being recommended?
- How will the procedure be performed?
- Will I have a remaining ovary (or portion of ovary)?
- What alternatives to oophorectomy are available to me?

### Alternatives

Depending on the specific condition that warrants an oophorectomy, it may be possible to modify the surgery so at least a portion of one ovary remains, allowing the woman to avoid early menopause. In the case of prophylactic oophorectomy, drugs such as tamoxifen may be administered to block the effects that estrogen may have on cancer cells.

## Open prostatectomy

### Definition

Open prostatectomy is a procedure for removal of an enlarged prostate gland.

### Purpose

The prostate gland is located at the base of the male urethra. The primary indication for open prostatectomy is benign prostatic hyperplasia (BPH), a condition whereby benign or noncancerous nodules grow in the prostate gland. The prostate gland is composed of smooth muscle cells, glandular cells, and cells that give the gland structure (stromal cells). A dense fibrous capsule surrounds the prostate gland. The glandular cells produce a milky fluid that mixes with seminal fluid and sperm to make semen. The prostate gland also produces a hormone called dihydrotestosterone (DHT) that has a major impact on the gland's development.

### Description

The prostate gland undergoes several changes as a man ages. The pea-size gland at birth grows only slightly during puberty and reaches its normal adult shape and size (similar to a walnut) when a male is in his early twenties. The prostate gland remains stable until the mid-forties. At that time in most men, the number of cells begins to multiply, and the gland starts to enlarge. The enlargement, called hyperplasia, is due to an increase in the number of cells. Cell proliferation in the prostates of older men can cause symptoms (referred to as lower urinary tract symptoms, LUTS), which often include:

- straining when urinating
- hesitation before urine flow starts
- dribbling at the end of urination or leakage afterward
- weak or intermittent urinary strain
- painful urination

During a digital rectal exam (B), the doctor may feel an enlargement of the prostate that can be benign or cancerous. If an open prostatectomy is needed, an incision may be made in the lower abdomen (C) or the perineal area (D). In either case, the prostate and any cancer is removed (E). (Illustration by GGS Information Services. Cengage Learning, Gale.)

## KEY TERMS

**Bladder mucosa**—Mucous coat of the bladder.

**Cerebrovascular accident**—Brain hemorrhage, also known as a stroke.

**Cystoscopy**—Examination of the bladder using a special instrument to visualize the organ.

**Cystotomy**—An incision in the bladder.

**Pulmonary embolus**—A thrombus that typically detaches from a deep vein of a lower extremity.

**Trendelenburg**—Position in which the head is low and the body and legs are on an inclined plane.

Other symptoms (called storage symptoms) sometimes appear, and may include:

- urgent need to urinate
- bladder pain when urinating
- increased frequency of urination, especially at night
- bladder irritation during urination

The cause of BPH is not fully understood. Currently, it is thought to be caused by a hormone that the prostate gland synthesizes, called dihydrotestosterone (DHT). The hormone is synthesized from testosterone.

Surgery is generally indicated for persons with moderate to severe symptoms, particularly if urinary retention is very poor or if the enlarged prostate (BPH) contributes to urinary tract infections, blood in the urine, bladder stones, or kidney problems.

Open prostatectomy is the treatment of choice for approximately 2–3% of BPH patients who have a very large prostate, a damaged bladder, or another serious related problem. Open prostatectomy is used when the prostate is so large (2.8–3.5 oz [80–100 g]) that **transurethral resection of the prostate** (TURP, a less invasive surgical procedure to remove a smaller prostate) cannot be performed. Additionally, open prostatectomy is indicated for males with:

- recurrent or persistent urinary tract infections.
- acute urinary distention.
- bladder outlet obstructions.
- recurrent blood in urine of prostate origin.
- pathological changes in the bladder, ureters, or kidneys due to prostate obstruction.

Contraindications to open prostatectomy (reasons not to do the procedure) include previous prostatectomy, prostate cancer, a small fibrous prostate

gland, and previous pelvic surgery that may obstruct access to the prostate gland.

## Demographics

The cause of BPH is not entirely known; however, the incidence increases with advancing age. Before 40 years of age, approximately 10% of males have BPH. A small amount of hyperplasia is present in 80% of males over 40 years old. Approximately 8–31% of males experience moderate to severe lower urinary tract symptoms (LUTS) in their fifties. By age 80, about 80% of men have LUTS. A risk factor is the presence of normally functioning testicles; research indicates that castration can minimize prostatic enlargement. It appears that the glandular tissues that multiply abnormally use male hormones produced in the testicles differently than the normal tissues do.

Approximately 10 million American men and 30 million men worldwide have symptoms of BPH. It is more prevalent in the United States and Europe, and less common among Asians. BPH is more common in men who are married rather than single, and there is a strong genetic correlation. A man's chance for developing BPH is greater if three or more family members have the condition.

## Description

Open prostatectomy can be performed by either the retropubic or suprapubic approach. The preferred anesthesia for open prostatectomy is a spinal or epidural nerve block. Regional anesthesia can help reduce blood loss during surgery, and lowers the risk of complications such as pulmonary embolus and postoperative deep vein thrombosis. **General anesthesia** may be used if the patient has an anatomic or medical contraindication for regional anesthesia.

### *Retropubic prostatectomy*

The retropubic prostatectomy is accomplished through a direct incision of the anterior (front) prostatic capsule. The overgrowth of glandular cells (hyperplastic prostatic adenoma) is removed. These are the cells forming a mass in the prostate because of their abnormal multiplication.

A **cystoscopy** is performed before the open prostatectomy. The patient lies on his back on the operating table, and is prepared and draped for this procedure. Following the cystoscopy, the patient is changed to a Trendelenburg (feet higher than head) position. The surgical area is shaved, draped, and prepared. A catheter is placed in the urethra to drain urine. An incision is made from the umbilicus to the pubic area. The

abdominal muscle (rectus abdominis) is separated, and a retractor is placed at the incision site to widen the surgical field. Further maneuvering is essential to clearly locate the veins (dorsal vein complex) and the bladder neck. Visualization of the bladder neck exposes the patient's main arterial blood supply to the prostate gland. Once the structures have been identified and the blood supply controlled, an incision is made deep into the level of the tumor. Scissors are used to dissect the prostatic tissue (prostatic capsule) from the underlying tissue of the prostatic tumor. The wound is closed after complete removal of the tumor and hemostasis (stoppage of bleeding) occurs.

The advantages of the retropubic prostatectomy include:

- direct visualization of the prostatic tumor.
- accurate incisions in the urethra, which will minimize the complication of urinary continence.
- excellent anatomic exposure and visualization of the prostate.
- clear visualization to control bleeding after tumor removal.
- little or no surgical trauma to the urinary bladder.

### *Suprapubic prostatectomy*

Suprapubic prostatectomy (also called transvesical prostatectomy) is a procedure to remove the prostatic overgrowth via a different surgical route. The suprapubic approach utilizes an incision of the lower anterior (front) bladder wall. The primary advantage over the retropubic approach is that the suprapubic route allows for direct visualization of the bladder neck and bladder mucosa. Because of this, the procedure is ideally suited for persons who have bladder complications, as well as obese men. The major disadvantage is that visualization of the top part of the tumor is reduced. Additionally, with the subrapubic approach, hemostasis (stoppage of bleeding during surgery) may be more difficult due to poor visualization after removal of the tumor.

Using a scalpel, a lower midline incision is made from the umbilicus to the pubic area. A cystotomy (incision into the bladder) is made, and the bladder inspected. Using electrocautery (a special tool that produces heat at the tip, useful for hemostasis or tissue excision) and scissors, dissection proceeds until the prostatic tumor is identified and removed. After maintaining hemostasis and arterial blood supply to the prostate, the incisions to the bladder and abdominal wall are closed.

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

The procedure is performed by a urological surgeon who typically completes one year of general surgery training, and four to five years of urology training. The procedure is usually performed in a large hospital.

## Diagnosis/Preparation

The presence of symptoms is indicative of the disease. Age also has an associated risk for an enlarged prostate, and can help establish diagnostic criteria.

Men must have a special blood test called the prostate specific antigen (PSA) test and routine digital rectal examination (DRE) before surgery. If the PSA levels and DRE are suspiciously indicative of prostate cancer, a transrectal **ultrasound** guided needle biopsy of the prostate must be performed before open prostatectomy, to detect the presence of prostate cancer.

Additionally, preoperative patients should have lower urinary tract studies, including urinary flow rate and post void residual urine in the bladder. Because most patients are age 60 or older, preoperative evaluation should also include a detailed history and **physical examination**; standard blood tests; chest x-ray; and **electrocardiogram** (EKG) to detect any possible preexisting conditions.

## Aftercare

Open prostatectomy is a major surgical operation requiring an inpatient hospital stay of four to seven days. Blood transfusions are generally not required due to improvements in surgical technique. Immediately after the operation, the surgeon must closely monitor urinary output and fluid status. On the first day after surgery, most patients are given a clear liquid diet and asked to sit up four times. Morphine sulfate, given via a patient controlled analgesic pump (IV), is used to control pain.

On the second postoperative day, the urethral catheter is removed if the urine does not contain blood. Oral pain medications are begun if the patient can tolerate a regular diet.

On the third postoperative day, the pelvic drain is removed if drainage is less than 75 ml in 24 hours. The patient should gradually increase activity. Follow-up with the surgeon is necessary following **discharge**.

## QUESTIONS TO ASK THE DOCTOR

- Why is an open prostatectomy recommended?
- What form of open prostatectomy (retropubic or suprapubic) will be used?
- What forms of anesthesia and pain relief will be given?
- Where will the incision be located?
- What are the risks of the procedure?
- Is the surgeon a board certified urologist?
- Is there an alternative to open prostatectomy?
- What are the chances of after effects, including erectile problems?

**from the hospital.** Full activity is expected to resume within four to six weeks after surgery.

### Risks

Improvements in surgical technique have lowered blood loss to a minimal level. For several weeks after open prostatectomy, patients may have urgency and urge incontinence. The severity of bladder problems depends on the patient's preoperative bladder status. Erectile dysfunction occurs in 3–5% of patients undergoing this procedure. Retrograde (backward flow) ejaculation occurs in approximately 50–80% of patients after open prostatectomy. The most common non-urologic risks include pulmonary embolism, myocardial infarction (heart attack), deep vein thrombosis, and cerebrovascular accident (stroke). The incidence of any one of these potentially adverse effects is less than 1%.

### Normal results

Normally, patients will not have the adverse effects of bleeding. Hematuria (blood in the urine) is typically resolved within two days after surgery. The patient should begin a regular diet and moderate increases in activity soon after surgery. His presurgical activity level should be restored within four to six weeks after surgery.

### Morbidity and mortality rates

The overall rate of morbidity and mortality is extremely low. The overall mortality (**death**) rate for open prostatectomy is approximately zero.

### Alternatives

For smaller prostates, treatment using medication may help to control abnormal prostatic growth. When the prostate gland is large (75 grams and bigger), surgery is indicated.

## Operating room

### Definition

An operating room (OR), also called surgery center, is the unit of a hospital where surgical procedures are performed.

### Purpose

An operating room may be designed and equipped to provide care to patients with a range of conditions, or it may be designed and equipped to provide specialized care to patients with specific conditions.

### Description

#### OR environment

Operating rooms are sterile environments. All personnel wear protective clothing called scrubs, as well as shoe covers, masks, caps, eye shields, and other coverings to prevent the spread of germs. The operating room is brightly lit and the temperature is very cool; operating rooms are air-conditioned to help prevent infection.

## KEY TERMS

**Advance directives**—Legal documents that increase a patient's control over medical decisions. A patient may select medical treatment in advance, in the event that he or she becomes physically or mentally unable to communicate his or her wishes. Advance directives either state what kind of treatment the patient wants to receive (living will), or authorize another person to make medical decisions for the patient when he or she is unable to do so (durable power of attorney).

**Anesthesiologist**—A specially trained physician who administers anesthesia.

**Arterial line**—A catheter inserted into an artery and connected to a physiologic monitoring system to allow direct measurement of oxygen, carbon dioxide, and invasive blood pressure.

**Catheter**—A small, flexible tube used to deliver fluids or medications. A catheter may also be used to drain fluid or urine from the body.

**Central venous line**—A catheter inserted into a vein and connected to a physiologic monitoring system to directly measure venous blood pressure.

**Chest tube**—A tube inserted into the chest to drain fluid and air from around the lungs.

**Critical care**—The multidisciplinary healthcare specialty that provides care to patients with acute, life-threatening illness or injury.

**Edema**—An abnormal accumulation of fluids in intercellular spaces in the body; causes swelling.

**Endotracheal tube**—A tube inserted through the patient's nose or mouth that functions as an airway and is connected to a ventilator.

**Foley catheter**—A tube inserted into the bladder to drain urine into an external bag.

**Gastrointestinal tube**—A tube surgically inserted into the stomach for feeding a patient who is unable to eat by mouth.

**Infectious disease team**—A team of physicians and hospital staff who help control the hospital environment to protect patients against harmful sources of infection.

**Inpatient surgery**—Surgery that requires an overnight stay of one or more days in the hospital. The number of days spent in the hospital after surgery depends on the type of procedure performed.

**Life support**—Methods of replacing or supporting a failing bodily function, such as using mechanical ventilation to support breathing. In treatable or curable conditions, life support is used temporarily to aid healing until the body can resume normal functioning.

**Nasogastric tube**—A tube inserted through the nose and throat and into the stomach for directly feeding the patient.

**Nothing by mouth (NPO)**—NPO refers to the time after which the patient is not allowed to eat or drink prior to a procedure or treatment.

**Outpatient surgery**—Also called same-day or ambulatory surgery. The patient arrives for surgery and returns home on the same day. Outpatient surgery can take place in a hospital, surgical center, or outpatient clinic.

**Swan-Ganz catheter**—Also called a pulmonary artery catheter, this is a type of tubing inserted into a large vessel in the neck or chest. It is used to measure the amount of fluid in the heart, and to determine how well the heart is functioning.

The patient is brought to the operating room in a wheelchair or a bed with wheels called a gurney. The patient is transferred to the operating table, which is narrow and has safety straps to keep him or her positioned correctly.

The monitoring equipment and anesthesia used during surgery are usually kept at the head of the operating table. The anesthesiologist sits here to monitor the patient's condition during surgery.

Depending on the nature of the surgery, various forms of anesthesia or sedation are administered. The surgical site is cleansed and surrounded by a sterile drape.

The instruments used during a surgical procedure are different for external and internal treatment; different tools are used on the outside and on the inside of the body. Once internal surgery is started, the surgeon uses smaller, more delicate devices.

### *OR equipment*

An operating room has special equipment such as respiratory and cardiac support, emergency resuscitative devices, patient monitors, and diagnostic tools.

### ***Life support and emergency resuscitative equipment***

Equipment for life support and emergency resuscitation includes:

- Heart-lung bypass machine, also called a cardiopulmonary bypass pump, which takes over for the heart and lungs during some surgeries, especially heart or lung procedures. The heart-lung machine removes carbon dioxide from the blood and replaces it with oxygen. A tube is inserted into the aorta to carry the oxygenated blood from the bypass machine to the aorta for circulation to the body. The heart-lung machine allows the heart's beating to be stopped during surgery.
- Ventilator, also called a respirator, which assists with or controls pulmonary ventilation. Ventilators consist of a flexible breathing circuit, gas supply, heating/humidification mechanism, monitors, and alarms. They are microprocessor-controlled and programmable, and regulate the volume, pressure, and flow of respiration.
- Infusion pump is a device that delivers fluids intravenously or epidurally through a catheter. Infusion pumps employ automatic, programmable pumping mechanisms to deliver continuous anesthesia, drugs, and blood infusions to the patient.
- Crash cart, also called resuscitation cart or code cart, is a portable cart containing emergency resuscitation equipment for patients who are "coding" (i.e., vital signs are in a dangerous range). The emergency equipment includes a defibrillator, airway intubation devices, resuscitation bag/mask, and medication box. Crash carts are strategically located in the operating room for immediate accessibility if a patient experiences cardiorespiratory failure.
- Intra-aortic balloon pump is a device that helps reduce the heart's workload and helps blood flow to the coronary arteries for patients with unstable angina, myocardial infarction, or those awaiting organ transplants. Intra-aortic balloon pumps use a balloon placed in the patient's aorta. The balloon is on the end of a catheter that is connected to the pump's console, which displays heart rate, pressure, and electrocardiogram (ECG) readings. The patient's ECG is used to time the inflation and deflation of the balloon.

### ***Patient monitoring equipment***

Patient monitoring equipment includes:

- Acute care physiologic monitoring system is a comprehensive patient monitoring system that can be configured to continuously measure and display various parameters via electrodes and sensors connected

to the patient. Parameters monitored may include the electrical activity of the heart via an ECG, respiratory (breathing) rate, blood pressure (noninvasive and invasive), body temperature, cardiac output, arterial hemoglobin oxygen saturation (blood oxygen level), mixed venous oxygenation, and end-tidal carbon dioxide.

- Pulse oximeter monitors the arterial hemoglobin oxygen saturation (oxygen level) of the patient's blood with a sensor clipped over the finger or toe.
- Intracranial pressure monitor measures the pressure of fluid in the brain in patients with head trauma or other conditions affecting the brain (such as tumors, edema, or hemorrhage). Intracranial pressure monitors are connected to sensors inserted into the brain through a cannula (tube) or bur hole. These devices signal elevated pressure and record or display pressure trends. Intracranial pressure monitoring may be a capability included in a physiologic monitor.

### ***Diagnostic equipment***

The use of diagnostic equipment may be required in the operating room. Mobile x-ray units are used for bedside radiography, particularly of the chest. These portable units use a battery-operated generator that powers an x-ray tube. Handheld portable clinical laboratory devices, called point-of-care analyzers, are used for blood analysis at the bedside. A small amount of whole blood is required, and blood chemistry parameters can be provided much faster than if samples were sent to the central laboratory.

### ***Other OR equipment***

Disposable OR equipment includes urinary (Foley) catheters to drain urine during surgery, catheters used for arterial and central venous lines to monitor blood pressure during surgery or to withdraw blood samples, Swan-Ganz catheters to measure the amount of fluid in the heart and to determine how well the heart is functioning, chest and endotracheal tubes, and monitoring electrodes.

### ***New surgical techniques***

Minimally invasive surgery, also called laparoscopic surgery, is an operative technique performed through a few small incisions, rather than one large incision. Through these small incisions, surgeons insert a laparoscope (viewing instrument that displays the site on a computer screen for easier viewing) and endoscopic instruments to perform the surgery.

**Robot-assisted surgery** allows surgeons to perform certain procedures through small incisions. In

robotic surgery, a surgeon sits at a console several feet from the operating table and uses a joystick, similar to that used for video games, to guide the movement of robotic arms that hold endoscopic instruments, as well as an endoscope (small camera). The surgeon uses the robotic arms to perform precise, fine hand movements and to provide access to parts of the body that are difficult to reach manually. In addition, robotic surgery provides a three-dimensional image, and the surgical field can be magnified to a greater extent than traditional or minimally invasive surgery. The goal of robotic surgery is to decrease incision size and **length of hospital stay**, while improving patient comfort and lessening recovery time.

Lasers are “scalpels of light” that offer new alternatives for some surgical procedures. Lasers can be used to cut, burn, or destroy abnormal or diseased tissue; shrink or destroy lesions or tumors; sculpt tissue; and seal blood vessels. Lasers may help surgeons perform some procedures more effectively than other traditional methods. Because lasers cause minimal bleeding, the operative area may be more clearly viewed by the surgeon. Lasers may also provide access to parts of the body that may not have been as easily reached manually.

### Surgery centers

Freestanding surgery centers are available in many communities, primarily for the purpose of providing outpatient surgical procedures. The patient should make sure that the surgery center has been accredited by the Joint Commission on Accreditation of Healthcare Organizations (JCAHO), a professionally sponsored program that stimulates a high quality of patient care in healthcare facilities. There is also an accreditation option that is available for **ambulatory surgery centers**.

Choosing a surgery center with experienced staff is important. Here are some questions to consider when choosing a surgery center:

- How many surgeries are performed annually and what are the outcomes and survival rates for those procedures?
- How does the surgery center's outcomes compare with the national average?
- Does the surgery center offer procedures to treat a particular disease?
- Does the surgery center have experience treating patients in certain age groups?
- How much does surgery cost at this facility?
- Is financial assistance available?
- If the surgery center is far from the patient's home, will accommodations be provided for caregivers?

## Ophthalmologic surgery

### Definition

Ophthalmologic surgery is a surgical procedure performed on the eye or any part of the eye.

### Purpose

Surgery on the eye is routinely performed to repair retinal defects, remove cataracts or cancer, or to repair eye muscles. The most common purpose of ophthalmologic surgery is to restore or improve vision.

### Demographics

Patients from the very young to very old have ocular conditions that warrant eye surgery. Two of the most common procedures are **phacoemulsification for cataracts** and elective refractive surgeries.

Cataract surgery is the most common ophthalmic procedure. More than 1.5 million cataract surgeries are performed in the United States each year. According to the National Eye Institute (NEI), more than half of all Americans age 80 or older have a cataract or have had cataract surgery.

Elective refractive surgeries, especially **laser in-situ keratomileusis (LASIK)**, attract younger patients in their 30s and 40s. Recently, the American Academy of Ophthalmology (AAO) estimated that 95% of the 1.8 million refractive surgery procedures performed in a year were **LASIK**.

### Description

The surgeon, **operating room** nurses, and an anesthesiologist are present for ophthalmologic surgery. For many eye surgeries, only a local anesthetic is used, and the patient is awake. The patient's eye area is scrubbed prior to surgery, and sterile drapes are placed over the shoulders and head. Heart rate and blood pressure are monitored throughout the procedure. The patient is required to lie still and, for some surgery, especially refractive surgery, he or she is asked to focus on the light of the operating microscope. A speculum is placed in the eye to hold it open throughout surgery.

Common ophthalmologic surgery tools include scalpels, blades, forceps, speculums, and scissors. Many ophthalmologic surgeries now use lasers, which decrease the operating time as well as recovery time.

Surgeries requiring suturing can take as long as two or three hours. These intricate surgeries sometimes require the skill of a corneal or vitreo-retinal

## KEY TERMS

**Ablation**—During LASIK, the vaporization of eye tissue.

**Cataract**—A clouding of the eye's lens that affects vision.

**Cornea**—The clear, curved tissue layer in front of the eye. It lies in front of the colored part of the eye (iris) and the black hole in the center of the iris (pupil).

**Glaucoma**—Disease of the eye characterized by increased pressure of the fluid inside the eye. Untreated, glaucoma can lead to blindness.

**Macular degeneration**—A condition usually associated with age in which the area of the retina called the macula is impaired due to hardening of the arteries (arteriosclerosis). This condition interferes with vision.

**Retina**—The inner, light-sensitive layer of the eye containing rods and cones; transforms the images it receives into electrical messages sent to the brain via the optic nerve.

specialist, and require the patient to be put under **general anesthesia**.

### *Refractive surgeries*

Refractive surgeries use an excimer laser to reshape the cornea. The surgeon creates a flap of tissue across the cornea with an instrument called a microkeratome, ablates the cornea for about 30 seconds, and then replaces the flap. The laser allows this surgery to take only minutes, without the use of **stitches**.

### *Trabeculectomy*

**Trabeculectomy** surgery uses a laser to open the drainage canals or make an opening in the iris to increase outflow of aqueous humor. The purpose is to lower intraocular pressure in the treatment of glaucoma.

### *Laser photocoagulation*

Laser photocoagulation is used to treat some forms of wet age-related macular degeneration. The procedure stops leakage of abnormal blood vessels by burning them to slow the progress of the disease.

## Diagnosis/Preparation

Patients complaining of any ocular problem that requires surgery will receive a similar initial examination. A complete patient history is taken, including the chief complaint. The patient needs to disclose any allergies, medication usage, family eye and medical histories, and vocational and recreational vision requirements.

The diagnostic exam should include measurement of visual acuity under both low and high illumination, biomicroscopy with pupillary dilation, stereoscopic fundus examination with pupillary dilation, assessment of ocular motility and binocularity, visual fields, evaluation of pupillary responses to rule out afferent pupillary defects, refraction, and measurement of intraocular pressure (IOP).

Other examination procedures include corneal mapping, a keratometer reading to determine the curvature of the central part of the cornea, and a slit lamp exam to determine any damage to the cornea and evidence of glaucoma and cataracts. A fundus exam also will be performed to check for retinal holes, and macular degeneration and disease.

The patient's overall health must also be considered. Poor general health will affect the ophthalmologic-surgery outcome. Surgeons may request a complete **physical examination**, in addition to the eye examination, prior to surgery.

### *Presurgery preparation*

Patients having ophthalmologic surgery usually must stop taking **aspirin**, or aspirin-like products, 10 days before surgery unless directed otherwise by the surgeon. Patients taking blood thinners also must check with their physician to find out when they should stop taking the medication before surgery. A number of pain relievers may affect outcomes, making it important for the patient to disclose all medication. Some prescription medicines have been known to cause postsurgical scarring or flecks under the corneal flap after LASIK.

To reduce the chance of infection, the surgeon may request that the patient begin using antibiotic drops before surgery. Depending on the procedure, the patient may also be advised to discontinue contact lens wear and stop using creams, lotions, make-up, or perfume. Patients may also be asked to scrub their eyelashes for a period of time to remove any debris.

Patients are advised not to drink alcoholic beverages at least 24 hours before and after the ophthalmic procedure.

Patients must usually avoid eating or drinking anything after midnight on the day before the surgery; however, some patients may be allowed to have clear liquids in the morning. It is important for patients to ask their physician for a list of foods and medications permitted on the morning of surgery. Some patients may take morning medications (with physician approval) with the exclusion of **diuretics**, insulin, or diabetes pills. Patients are advised to dress comfortably for the surgery, and wear shirts that will not have to pass over the head.

Pre-surgical tests sometimes are administered when the patient arrives for surgery. For refractive surgeries, this ensures the laser is set for the correct refractive error. Before cataract surgery, measurements help determine the refractive power of the intraocular lens (IOL). Other tests, such as a **chest x ray**, blood work, or **urinalysis**, may also be requested depending on the patient's overall health.

Most ophthalmic surgeries are done on an outpatient basis, and patients must arrange for someone to take them home after the procedure.

Before surgery, doctors will review the pre-surgical tests and instill any dilating eye drops, antibiotic drops, and a corticosteroid or nonsteroidal anti-inflammatory drops as needed. Anesthetic eye drops also will be administered. Many ophthalmologic surgeries are performed under a local anesthetic, and patients remain in an awake but relaxed state.

## Aftercare

After surgery, the patient is monitored in a recovery area. For most outpatient procedures, the patient is advised to rest for at least 24 hours until he or she returns to the surgeon's office for follow-up care. Over-the-counter (OTC) medications are usually advised for pain relief, but patients should check with their doctor to see what is recommended. Some pain relievers interfere with surgical outcomes. Patients may also use ice packs to help ease pain.

Some patients may experience slight drooping or bruising of the eye. This condition improves as the eye heals. Severe pain, nausea, or vomiting should be reported to the surgeon immediately.

After surgery, patients may be advised not to stoop, lift heavy objects, **exercise** vigorously, or swim. Patients may also be required to wear an eye shield while sleeping, and sunglasses or some type of protective lens during the day to avoid injury. Wearing make-up may be prohibited for weeks after surgery. The patient may be restricted from driving and air travel.

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

Ophthalmologists and optometrists may detect ophthalmic problems; however, only an ophthalmologist can perform surgery. An ophthalmologist has received specialized training in diseases of the eye and their surgical treatment. Some ophthalmologists further specialize in certain areas of the eye, such as corneal or vitreo-retinal specialists. Depending on the severity of the disease, the general ophthalmologist may refer the patient to a specialist for treatment.

An anesthesiologist may be on hand during surgery to administer the local anesthetic. Surgical nurses will assist the ophthalmologist in the operating room, and assist the patient preoperatively and postoperatively.

Most ophthalmic surgery is performed on an outpatient basis. Ambulatory surgery centers designed for ophthalmologic surgery are commonly used. Surgery may also be performed in hospital operating rooms designed for outpatient surgeries.

Patients usually have their first postoperative visit the day after the eye surgery. Subsequent exams are commonly scheduled at one, three, and six to eight weeks following surgery. This schedule depends on the patient's healing, and any complications he or she might experience.

Some patients will be required to instill eye drops for a number of weeks after surgery to prevent infection, pain, and to lessen inflammation. Eye drops also are used to lower intraocular pressure. In some cases, correct eye drop usage is critical to a successful surgery outcome.

### Risks

Complications may occur during any surgery. Ophthalmologic surgery, however, is usually very safe.

Some risks include:

- Undercorrection or overcorrection in refractive surgery. Undercorrected refractive surgery patients usually can be treated with an enhancement, but overcorrected patients will need to use eyeglasses or contact lenses.
- Debilitating symptoms. These include glare, halos, double vision, and poor nighttime vision. Some

## QUESTIONS TO ASK THE DOCTOR

- If both eyes are diseased, will they be treated simultaneously?
- Will the eyes need to rest after surgery? Will protective lenses be required following the procedure?
- Will eyeglasses be needed?
- How many times has the surgeon performed this specific procedure?
- Should the physician be contacted if pain develops after the surgery?
- When can normal activities, such as driving, be resumed?

patients may also lose contrast sensitivity. These symptoms may be temporary or permanent.

- Dry eye. Some patients are treated with artificial tears or punctal plugs.
- Retinal detachment. The retina can become detached by the surgery if this part of the eye has any weakness when the procedure is performed. This may not occur for weeks or months.
- Endophthalmitis. An infection in the eyeball is a complication that is less common today because of newer surgery techniques and antibiotics.

Other serious complications that may occur are blindness, glaucoma, or hemorrhage.

### Normal results

Normal results include restored or improved vision, and a much improved quality of life. Specific improvements depend on the type of ophthalmologic surgery performed, and the type of ocular ailment being treated.

### Morbidity and mortality rates

**Death** from ophthalmologic surgery is rare. However, complications can still arise from the use of general anesthesia. With most ophthalmic surgeries requiring only local anesthetic, that risk has been widely eliminated.

Blindness, which was sometimes caused by serious infection, has also been reduced because of more effective **antibiotics**.

## Alternatives

Some medications can be used to treat certain ophthalmic conditions. For example, surgery for glaucoma is performed only in patients who do not respond to medication. Patients with myopia (nearsightedness), hyperopia (farsightedness), or presbyopia (difficulty focusing up close) can wear contact lenses or eyeglasses instead of having refractive surgery to improve their refractive errors.

## Ophthalmoscopy

### Definition

Ophthalmoscopy involves the use of a lighted scope (ophthalmoscope) that has a very bright light and a number of magnifying lenses. The scope used may be

a handheld scope that provides both light source and magnifying lenses (direct ophthalmoscope). Alternatively, the examiner may wear a binocular device and hold a lens to perform this examination (indirect ophthalmoscope). The ophthalmoscope is used to examine the back of the eye (called the fundus). The fundus is lined by the light-sensitive tissue of the retina, and also contains the optic disc, choroids, and blood vessels.

### Purpose

Ophthalmoscopy is performed during the course of all routine physical examinations. Additionally, ophthalmoscopy can be performed when symptoms suggest the possible presence of a condition that could affect the eyes. For example, eye diseases such as macular degeneration, glaucoma, retinal detachment, or tumors on the optic nerve can be diagnosed or monitored through ophthalmoscopy. Ophthalmoscopy may also be used to evaluate and monitor the deleterious effects of diseases of other body systems that may also affect the health of the eye, including such conditions as high blood pressure, atherosclerosis, vascular disease, diabetes, and brain tumors.

### Description

Ophthalmoscopy is performed in a dark room. The bright light from the ophthalmoscope will be shined into each of the patient's eyes, and the examiner will change the internal lens of the scope to the power that provides the clearest image. The scope will be moved so that all quadrants of the eye can be examined. The individual undergoing the examination may be asked to move his or her eyes in various directions. An instrument to measure pressure in the eyeball may be briefly applied to each eyeball to test for glaucoma. The entire examination is usually completed in under five to ten minutes.

### Preparation

There is no advance preparation required for ophthalmoscopy. In some cases, such as indirect ophthalmoscopy, drops which can dilate the pupils may be put into the patient's eyes several minutes prior to the examination. When the pupils are dilated, it can make the examination easier to perform, and the structures within the eye can be more clearly visualized by the examiner.

### Aftercare

When patients have received dilating eyedrops prior to ophthalmoscopy, they should wear sunglasses

## KEY TERMS

**Atherosclerosis**—A disease in which plaques of material along the arterial walls cause the arteries to become abnormally hard and stiff. This disease puts people at higher risk for heart attack and stroke.

**Choroid**—Blood vessels which run between the white of the eye (sclera) and the retina, carrying nutrients and oxygen to the retina.

**Glaucoma**—A disease in which there is excessive fluid pressure within the eyeball.

**Macular degeneration**—A progressive disease in which the central portion of the retina (the macula) is gradually destroyed.

**Optic disc**—A visually inactive portion of the retina from which the optic nerve and blood vessels emerge.

**Retina**—The light-sensing tissue within the eye that sends signals to the brain in order to generate a visual image.

while outside for the next several hours to protect their eyes from sunlight. Some people find that their vision is affected by the dilatation of their pupils. In this case, they should be advised not to drive until they feel that their vision has returned to normal. Other than these precautions, there is no aftercare necessary following ophthalmoscopy. The patient can immediately return to a normal diet and normal activities.

### Risks

Ophthalmoscopy poses no risk to the patient. Under rare circumstances, patients may have a reaction to the dilating eyedrops, such as nausea, vomiting, dry mouth, flushing, dizziness, or a glaucoma episode.

### Normal results

Normal results of ophthalmoscope reveal normal anatomy of the back of the eye.

### Abnormal results

Abnormalities in the ophthalmoscopic examination may indicate a variety of eye disease, trauma to the eye, or other systemic diseases that have effects on the structure or functioning of structures within the eye.

## Oral glucose tolerance test

### Definition

The oral glucose tolerance test (OGTT) is a series of blood tests that are used to evaluate an individual's response to drinking a standard quantity of a specific glucose-containing solution. The patient drinks the solution, and then the blood is drawn at specific intervals over the next several hours. Each blood test measures the amount of glucose (a particular form of simple sugar) in the blood. The tests are used to evaluate patients for the possibility that they have diabetes.

When carbohydrates are ingested, they are broken down in the intestines into component parts, including sugars such as glucose. Glucose is absorbed from the small intestine into the bloodstream. It circulates throughout the body and is used by all of the body's tissues and organs to generate the energy necessary for their normal functioning. In order for glucose to enter the body's cells, insulin must be present. Insulin is a hormone produced in and excreted by the pancreas. Insulin functions to allow the transport of glucose into the cells of the body, as well as being involved in the body's storage of excess glucose in the form of glycogen or triglycerides.

The blood levels of glucose and insulin are intimately related. When carbohydrates are metabolized after a meal, the blood glucose begins to rise. Under normal circumstances, the pancreas then secretes insulin, in an amount relative to the blood glucose elevation. Between meals, or after heavy exertion, glucose levels may begin to drop below a safe threshold for the body's cells (particular cells of the brain and nervous system). In response to this lowering of blood glucose, the pancreas secretes a different hormone, called glucagon. Glucagon prompts the liver to convert glycogen into glucose, thereby elevating the blood glucose back into a safe range.

Abnormal levels of blood glucose can be life-threatening. High blood glucose is termed hyperglycemia; low blood glucose is termed hypoglycemia. Either of these conditions can result in organ failure, severe brain damage, coma, or **death**. Diabetes occurs when the pancreas fails to produce normal amounts of insulin, or when it completely stops producing any insulin at all (this is often referred to as insulin-dependent or type I diabetes). Diabetes can also occur when cells of the body become less responsive to the effects of insulin (this is often referred to as insulin-resistance, or type II diabetes). Diabetes causes abnormal perturbations of the **serum glucose level**. Over time, chronic high levels of serum glucose (which may occur in poorly controlled diabetes) can result in severe damage to the heart, the eyes, the kidneys, the circulatory system, and the nervous system. In diabetics, sudden, acute increases in the serum glucose level can result in the condition called diabetic ketoacidosis, in which the extremely high levels of blood glucose lead a life-threatening illness. Diabetics can also suffer from sudden drops in serum glucose levels; if untreated, glucose deprivation affecting the organs and tissues of the body can also be life-threatening.

Women are at risk of developing gestational diabetes during pregnancy. While this condition usually resolves after the birth of the baby, and rarely leads to a permanent diagnosis of diabetes, untreated gestational diabetes can result in problems for the baby as well as the mother. Gestational diabetes in early pregnancy can cause birth defects (particularly of the brain and/or heart) and increase the chance of miscarriage. Gestational diabetes in the second and third trimesters can cause the baby to grow very large (termed macrosomia). The baby's size can result in problems for the mother during labor and delivery. Additionally, once the baby is born, it can suffer sudden hypoglycemia. In utero, the baby will have acclimated to its mother's high serum glucose levels by producing high levels of insulin. After birth, suddenly deprived of that glucose, the baby's relatively high insulin levels can result in severe hypoglycemia. If the mother is known to have gestational diabetes, then the baby will be monitored more carefully for potential drops in its blood glucose, and, if necessary, treatment with an IV solution containing glucose can be instituted rapidly.

### Purpose

An oral glucose tolerance test is usually performed when there is a suspicion that an individual has Type II diabetes, for example when a serum glucose level has revealed an abnormality, when there is a strong family history of diabetes, when an individual has specific risk

factors for diabetes (such as being overweight), or when an individual is experiencing symptoms suggestive of diabetes (excessive thirst and/or hunger, urinary frequency, unintentional weight loss, severe fatigue and weakness, and poor healing). Additionally, an oral glucose tolerance test is almost always ordered as a routine part of prenatal care during the second trimester of pregnancy, usually between 24 and 28 weeks of pregnancy.

### Precautions

Serum glucose levels can be affected by a number of medications. Patients who are on these medications should inform their doctor, so that test results can be interpreted appropriately. Medications that may affect serum glucose levels include birth control pills, high blood pressure medications, phenytoin, furosemide, triamterene, hydrochlorothiazide, niacin, propranolol, and steroid medications. Additionally, the use of alcohol, caffeine, or recent illness, infection or emotional distress may affect test results.

Patients who are taking anticoagulant medications should inform their healthcare practitioner, since this may increase their chance of bleeding or bruising after a blood test.

### Description

This test requires blood to be drawn from a vein (usually one in the forearm), generally by a nurse or phlebotomist (an individual who has been trained to draw serum). The initial blood draw is performed prior to the patient drinking the glucose solution. The other blood draws are performed at set intervals over the three or so hours after the solution has been ingested.

A tourniquet is applied to the arm above the area where the needle stick will be performed. The site of the needle stick is cleaned with antiseptic, and the needle is inserted. The serum is collected in vacuum tubes. After collection, the needle is withdrawn, and pressure is kept on the serum draw site to stop any bleeding and decrease bruising. A bandage is then applied.

### Preparation

The oral glucose tolerance test should only be performed when the individual is in perfectly good health and normally ambulatory/active. For the 72 hours prior to undergoing the OGTT, the individual should be instructed to eat a high-carbohydrate diet (150-200 grams of carbohydrate per day). The test is done on a fasting basis, meaning that nothing should be eaten or drunk after midnight prior to the test (the

## KEY TERMS

**Gestational diabetes**—A type of diabetes that occurs during pregnancy. Untreated, it can cause severe complications for the mother and the baby. However, it usually does not lead to long-term diabetes in either the mother or the child.

**Glucose**—A simple sugar that is the product of carbohydrate metabolism. It is the major source of energy for all of the organs and tissues of the body.

**Glucagon**—A hormone produced in the pancreas that is responsible for elevating blood glucose when it falls below a safe level for the body's organs and tissues.

**Glycogen**—The form in which glucose is stored in the body.

**Hyperglycemia**—Elevated blood glucose levels.

**Hypoglycemia**—Low blood glucose levels.

**Insulin**—A hormone produced by the pancreas that is responsible for allowing the body's cells to utilize glucose. The deficiency or absence of insulin is one of the causes of the disease diabetes.

**Ketoacidosis**—A potentially life-threatening condition in which abnormally high blood glucose levels result in the blood become too acidic.

**Macrosomia**—The term used to describe a newborn baby with an abnormally high birth weight.

**Pancreas**—An organ located near the liver and stomach, responsible for various digestive functions. The pancreas produces insulin and glucagon, hormones that are responsible for maintaining safe blood levels of glucose.

fast should last a minimum of eight and a maximum of sixteen hours). The morning of the exam, the individual should be instructed not to smoke or drink any caffeinated beverages.

Upon arrival at the laboratory, a baseline fasting serum blood glucose will be drawn. Following this, the individual will be asked to drink a solution that contains 75 grams of glucose (pregnant women will drink a 100-gram solution). The solution must be ingested in no more than five minutes. Serum blood glucose levels will be drawn at 30- to 60-minute intervals over the next several hours. A classic oral glucose tolerance test involves five blood draws over the course of the three hour testing period. An abbreviated oral glucose tolerance involves a baseline serum glucose determination, a two-hour wait, and then a second serum glucose level.

## Aftercare

As with any blood tests, discomfort, bruising, and/or a very small amount of bleeding is common at the puncture site. Immediately after the needle is withdrawn, it is helpful to put pressure on the puncture site until the bleeding has stopped. This decreases the chance of significant bruising. Warm packs may relieve minor discomfort. Some individuals may feel briefly woozy after a serum test, and they should be encouraged to lie down and rest until they feel better.

## Risks

Basic blood tests, such as serum glucose levels, do not carry any significant risks, other than slight bruising and the chance of brief dizziness.

## Results

Normal results of a random serum glucose test range from 70-125 milligrams per deciliter (mg/dL). A normal serum glucose level at the two-hour point (two hours after ingesting the glucose solution) is less than 140 mg/dL. During the course of the two hours, any serum glucose levels should be less than 200 mg/dL.

## High levels

High serum glucose levels suggest the possibility of diabetes. However, a single high, random serum glucose level is not sufficient for definitively diagnosing diabetes. The American Diabetes Association has specific criteria that must be met in order to diagnose diabetes. They require that results are verified through testing on a minimum of two different days. The oral glucose tolerance is considered to be positive for diabetes when the blood draw at the two-hour point measures 200 mg/dL or higher.

Some individuals don't meet the criteria for an actual diagnosis of diabetes, but have a higher-than-normal fasting serum glucose level, also known as an impaired fasting glucose (ranging from 100 mg/dL to 125 mg/dL), and an elevated 2-hour serum glucose level (ranging between 140 and 199 mg/dL). These individuals are thought to have an increased risk of eventually developing diabetes, and should be followed closely. Some practitioners believe that these serum glucose levels are indicative of "prediabetes."

When an oral glucose tolerance test is performed on a pregnant woman, gestational diabetes is diagnosed if the test reveals any two of the following criteria:

- A fasting serum glucose level greater than 95 mg/dL
- A serum glucose level greater than 180 mg/dL, one hour after ingesting the standardized glucose solution

- A serum glucose level greater than 155 mg/dL, two hours after ingesting the standardized glucose solution
- A serum glucose level greater than 140 mg/dL, three hours after ingesting the standardized glucose solution

A number of conditions other than diabetes can cause high serum glucose levels, including:

- Severe stress
- Heart attack
- Stroke
- Cushing's syndrome
- Steroid medications
- Pheochromocytoma
- Polycystic ovarian disease
- Acromegaly (elevated growth hormone)

### *Low levels*

Low serum glucose levels may be due to:

- The presence of an insulinoma (a tumor that secretes insulin)
- Addison's disease
- Hypothyroidism (underactive thyroid)
- Pituitary gland tumor
- Liver disease, including cirrhosis
- Kidney disease
- Malnutrition
- Eating disorders, including anorexia nervosa
- Inappropriate doses of medicines used to treat diabetes, such as insulin or oral hypoglycemic agents

## **Orchiectomy**

### **Definition**

Orchiectomy is the surgical removal of one or both testicles, or testes, in the human male. It is also called an orchidectomy, particularly in British publications. The removal of both testicles is known as a bilateral orchiectomy, or castration, because the person is no longer able to reproduce. Emasculation is another word that is sometimes used for castration of a male. Castration in women is the surgical removal of both ovaries (bilateral **oophorectomy**).

### **Purpose**

An orchiectomy is done to treat cancer or, for other reasons, to lower the level of testosterone, the primary male sex hormone, in the body. Surgical removal of a testicle is the usual treatment if a tumor is found within the gland itself, but an orchiectomy may also be performed to treat prostate cancer or cancer of the male breast, as testosterone causes these cancers to grow and metastasize (spread to other parts of the body). An orchiectomy is sometimes done to prevent cancer when an undescended testicle is found in a patient who is beyond the age of puberty.

A bilateral orchiectomy is commonly performed as one stage in male-to-female (MTF) gender reassignment surgery. It is done both to lower the levels of male hormones in the patient's body and to prepare the genital area for later operations to construct a vagina and external female genitalia.

Some European countries and four states in the United States (California, Florida, Montana, and Texas) allow convicted sex offenders to request surgical castration to help control their sexual urges. This option is considered controversial in some parts of the legal system. A small number of men with very strong sex drives request an orchiectomy for religious reasons; it should be noted, however, that official Roman Catholic teaching is opposed to the performance of castration for spiritual purity.

### **Demographics**

#### **Cancer**

Cancers in men vary widely in terms of both the numbers of men affected and the age groups most likely to be involved. Prostate cancer is the single most common malignancy affecting American men over the age of 50; about 220,000 cases are reported each year. According to the Centers for Disease Control and Prevention

**In an orchiectomy, the scrotum is cut open (A). Testicle covering is cut to expose the testis and spermatic cord (B). The cord is tied and cut, removing the testis (C), and the wound is repaired (D).** (Illustration by GGS Information Services. Cengage Learning, Gale.)

(CDC), 31,000 men in the United States die every year from prostate cancer. African-American men are almost 70% more likely to develop prostate cancer than either Caucasian or Asian-American men; the reasons for this difference are not yet known. Other factors that increase a man's risk of developing prostate cancer include a diet high in red meat, fat, and dairy products, and a family history of the disease. Men whose father or brother(s) had prostate cancer are twice as likely as other men to develop the disease themselves. Today, however, there are still no genetic tests available for prostate cancer.

Testicular cancer, on the other hand, frequently occurs in younger men; in fact, it is the most common cancer diagnosed in males between the ages of 15 and 34. The rate of new cases in the United States each year is about 3.7 per 100,000 people. The incidence of testicular cancer has been rising in the developed countries at a rate of about 2% per year since 1970. It is not yet known whether this increase is a simple reflection of improved diagnostic techniques or whether there are other causes. There is some variation among racial and ethnic groups, with men of Scandinavian background having higher than average rates of testicular cancer, and African-American men having a lower than average incidence. Testicular cancer occurs most often in males in one of three age groups: boys 10 years old or younger; adult males between the ages of 20 and 40; and men over 60.

Other risk factors for testicular cancer include:

- Cryptorchidism, which is a condition in which a boy's testicles do not move down from the abdomen into the scrotum at the usual point in fetal development. It is also called undescended testicle(s). Ordinarily, the testicles descend before the baby is born; however, if the baby is born prematurely, the scrotal sac may be empty at the time of delivery. About 3–4% of full-term male infants are born with undescended testicles. Men with a history of childhood cryptorchidism are three to 14 times more likely to develop testicular cancer.
- Family history of testicular cancer.
- A mother who took diethylstilbestrol (DES) during pregnancy. DES is a synthetic hormone that was prescribed for many women between 1938 and 1971 to prevent miscarriage. It has since been found to increase the risk of certain types of cancer in the offspring of these women.
- Occupational and environmental factors. Separate groups of researchers in Germany and New Zealand reported in 2003 that firefighters have an elevated risk of testicular cancer compared to control subjects. The specific environmental trigger is not yet known.

### *Gender reassignment*

Statistics for orchiectomies in connection with gender reassignment surgery are difficult to establish

## KEY TERMS

**Androgen**—Any substance that promotes the development of masculine characteristics in a person. Testosterone is one type of androgen; others are produced in the adrenal glands located above the kidneys.

**Bilateral**—On both sides. A bilateral orchiectomy is the removal of both testicles.

**Capsule**—A general medical term for a structure that encloses another structure or body part. The capsule of the testicle is the membrane that surrounds the glandular tissue.

**Castration**—Removal or destruction by radiation of both testicles (in a male) or both ovaries (in a female), making the individual incapable of reproducing.

**Cryptorchidism**—A developmental disorder in which one or both testes fail to descend from the abdomen into the scrotum before birth.

**Emasculation**—Another term for castration of a male.

**Epidural**—A type of regional anesthetic delivered by injection into the area around the patient's lower spine. An epidural numbs the body below the waist but allows the patient to remain conscious throughout the procedure.

**Gender identity disorder (GID)**—A mental disorder in which a person strongly identifies with the other sex and feels uncomfortable with his or her biological sex. It occurs more often in males than in females.

**Gender reassignment surgery**—The surgical alteration and reconstruction of a person's sex organs to resemble those of the other sex as closely as possible; it is sometimes called sex reassignment surgery.

**Inguinal**—Referring to the groin area.

**Metastasis**—A process in which a malignant tumor transfers cells to a part of the body not directly connected to its primary site. A cancer that has spread from its original site to other parts of the body is said to be metastatic.

**Oophorectomy**—Removal of one or both ovaries in a woman.

**Orchiectomy**—Surgical removal of one or both testicles in a male. It is also called an orchidectomy.

**Scrotum**—The pouch of skin on the outside of the male body that holds the testes.

**Spermatic cord**—A tube-like structure that extends from the testicle to the groin area. It contains blood vessels, nerves, and a duct to carry spermatic fluid.

**Subcapsular**—Inside the outer tissue covering of the testicle. A subcapsular orchiectomy is a procedure in which the surgeon removes the inner glandular tissue of the testicle while leaving the outer capsule intact.

**Testis (plural, testes)**—The medical term for a testicle.

**Testosterone**—The major male sex hormone, produced in the testes.

**Tumor marker**—A circulating biochemical compound that indicates the presence of cancer. Tumor markers can be used in diagnosis and in monitoring the effectiveness of treatment.

**Urology**—The branch of medicine that deals with disorders of the urinary tract in both males and females, and with the genital organs in males.

because most patients who have had this type of surgery prefer to keep it confidential. Persons undergoing the hormonal treatments and periods of real-life experience as members of the other sex that are required prior to genital surgery frequently report social rejection, job discrimination, and other negative consequences of their decision. Because of widespread social disapproval of surgical gender reassignment, researchers do not know the true prevalence of gender identity disorders in the general population. Early estimates were 1:37,000 males and 1:107,000 females. A recent study in the Netherlands, however, maintains that a more accurate estimation is 1:11,900 males and 1:30,400 females. In any case, the number of surgical procedures is lower than the number of patients diagnosed with gender identity disorders.

## Description

There are three basic types of orchiectomy: simple, subcapsular, and inguinal (or radical). The first two types are usually done under local or epidural anesthesia, and take about 30 minutes to perform. An inguinal orchiectomy is sometimes done under **general anesthesia**, and takes between 30 minutes and an hour to complete.

### Simple orchiectomy

A simple orchiectomy is performed as part of gender reassignment surgery or as palliative treatment for advanced cancer of the prostate. The patient lies flat on an operating table with the penis taped against the abdomen. After the anesthetic has been given, the

surgeon makes an incision in the midpoint of the scrotum and cuts through the underlying tissue. The surgeon removes the testicles and parts of the spermatic cord through the incision. The incision is closed with two layers of sutures and covered with a surgical dressing. If the patient desires, a prosthetic testicle can be inserted before the incision is closed to give the appearance of a normal scrotum from the outside.

### ***Subcapsular orchiectomy***

A subcapsular orchiectomy is also performed for treatment of prostate cancer. The operation is similar to a simple orchiectomy, with the exception that the glandular tissue is removed from the lining of each testicle rather than the entire gland being removed. This type of orchiectomy is done primarily to keep the appearance of a normal scrotum.

### ***Inguinal orchiectomy***

An inguinal orchiectomy, which is sometimes called a radical orchiectomy, is done when testicular cancer is suspected. It may be either unilateral, involving only one testicle, or bilateral. This procedure is called an inguinal orchiectomy because the surgeon makes the incision, which is about 3 in (7.6 cm) long, in the patient's groin area rather than directly into the scrotum. It is called a radical orchiectomy because the surgeon removes the entire spermatic cord as well as the testicle itself. The reason for this complete removal is that testicular cancers frequently spread from the spermatic cord into the lymph nodes near the kidneys. A long non-absorbable suture is left in the stump of the spermatic cord in case later surgery is necessary.

After the cord and testicle have been removed, the surgeon washes the area with saline solution and closes the various layers of tissues and skin with various types of sutures. The wound is then covered with sterile gauze and bandaged.

## **Diagnosis/Preparation**

### ***Diagnosis***

**CANCER.** The doctor may suspect that a patient has prostate cancer from feeling a mass in the prostate in the course of a rectal examination, from the results of a transrectal **ultrasound** (TRUS), or from elevated levels of prostate-specific antigen (PSA) in the patient's blood. PSA is a tumor marker, or chemical, in the blood that can be used to detect cancer and monitor the results of therapy. A definite diagnosis of prostate cancer, however, requires a tissue biopsy. The tissue sample can usually be obtained with the needle technique. Testicular cancer is suspected when the doctor feels a mass in the

patient's scrotum, which may or may not be painful. In order to perform a biopsy for definitive diagnosis, however, the doctor must remove the affected testicle by radical orchiectomy.

**GENDER REASSIGNMENT.** Patients requesting gender reassignment surgery must undergo a lengthy process of physical and psychological evaluation before receiving approval for surgery. The Harry Benjamin International Gender Dysphoria Association (HBIGDA), which is presently the largest worldwide professional association dealing with the treatment of gender identity disorders, has published standards of care that are followed by most surgeons who perform genital surgery for gender reassignment. HBIGDA stipulates that a patient must meet the diagnostic criteria for gender identity disorders as defined by either the *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition (DSM-IV) or the *International Classification of Diseases-10* (ICD-10).

### ***Preparation***

All patients preparing for an orchiectomy will have standard blood and urine tests before the procedure. They are asked to discontinue aspirin-based medications for a week before surgery and all non-steroidal anti-inflammatory drugs (NSAIDs) two days before the procedure. Patients should not eat or drink anything for the eight hours before the scheduled time of surgery.

Most surgeons ask patients to shower or bathe on the morning of surgery using a special antibacterial soap. They should take extra time to lather, scrub, and rinse their genitals and groin area.

Patients who are anxious or nervous before the procedure are usually given a sedative to help them relax.

**CANCER.** Patients who are having an orchiectomy as treatment for testicular cancer should consider banking sperm if they plan to have children following surgery. Although it is possible to father a child if only one testicle is removed, some surgeons recommend banking sperm as a precaution in case the other testicle should develop a tumor at a later date.

**GENDER REASSIGNMENT.** Most males who have requested an orchiectomy as part of male-to-female gender reassignment have been taking hormones for a period of several months to several years prior to surgery, and have had some real-life experience dressing and functioning as women. The surgery is not performed as an immediate response to the patient's request.

Because the standards of care for gender reassignment require a psychiatric diagnosis as well as a **physical examination**, the surgeon who is performing the orchiectomy should receive two letters of evaluation and recommendation by mental health professionals, preferably one from a psychiatrist and one from a clinical psychologist.

### Aftercare

Patients who are having an orchiectomy in an ambulatory surgery center or other outpatient facility must have a friend or family member to drive them home after the procedure. Most patients can go to work the following day, although some may need an additional day of rest at home. Even though it is normal for patients to feel nauseated after the anesthetic wears off, they should start eating regularly when they get home. Some pain and swelling is also normal; the doctor will usually prescribe a pain-killing medication to be taken for a few days.

Other recommendations for aftercare include:

- Drinking extra fluids for the next several days, except for caffeinated and alcoholic beverages.
- Avoiding sexual activity, heavy lifting, and vigorous exercise until the follow-up appointment with the doctor.
- Taking a shower rather than a tub bath for a week following surgery to minimize the risk of absorbable stitches dissolving prematurely.
- Applying an ice pack to the groin area for the first 24–48 hours.
- Wearing a jock strap or snug briefs to support the scrotum for two weeks after surgery.

Some patients may require psychological counseling following an orchiectomy as part of their long-term aftercare. Many men have very strong feelings about any procedure involving their genitals, and may feel depressed or anxious about their bodies or their relationships after genital surgery. In addition to individual psychotherapy, support groups are often helpful. There are active networks of prostate cancer support groups in Canada and the United States as well as support groups for men's issues in general.

Long-term aftercare for patients with testicular cancer includes frequent checkups in addition to radiation treatment or chemotherapy. Patients with prostate cancer may be given various hormonal therapies or radiation treatment.

### Risks

Some of the risks for an orchiectomy done under general anesthesia are the same as for other procedures. They include deep venous thrombosis, heart or breathing problems, bleeding, infection, or reaction to the anesthesia. If the patient is having epidural anesthesia, the risks include bleeding into the spinal canal, nerve damage, or a spinal headache.

Specific risks associated with an orchiectomy include:

- loss of sexual desire (This side effect can be treated with hormone injections or gel preparations.)
- impotence
- hot flashes similar to those in menopausal women, controllable by medication
- weight gain of 10–15 lb (4.5–6.8 kg)
- mood swings or depression
- enlargement and tenderness in the breasts
- fatigue
- loss of sensation in the groin or the genitals
- osteoporosis (Men who are taking hormone treatments for prostate cancer are at greater risk of osteoporosis.)

An additional risk specific to cancer patients is recurrence of the cancer.

### Normal results

#### *Cancer*

Normal results depend on the location and stage of the patient's cancer at the time of surgery. Most prostate cancer patients, however, report rapid relief from cancer symptoms after an orchiectomy. Patients with testicular cancer have a 95% survival rate five years after surgery if the cancer had not spread beyond the testicle. Metastatic testicular cancer, however, has a poorer prognosis.

#### *Gender reassignment*

Normal results following orchiectomy as part of a sex change from male to female are a drop in testosterone levels with corresponding decrease in sex drive and gradual reduction of such masculine characteristics as beard growth. The patient may choose to have further operations at a later date.

### Morbidity and mortality rates

Orchiectomy by itself has a very low rate of morbidity and mortality. Patients who are having an orchiectomy as part of cancer therapy have a higher risk of **dying** from the cancer than from testicular surgery.

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

Orchiectomy performed as part of cancer therapy may be done in a hospital under general anesthesia, but is most often done as an outpatient procedure in a urology clinic or similar facility. Most surgeons who perform orchiectomies to treat cancer are board-certified urologists or general surgeons.

Orchiectomies performed as part of gender reassignment surgery are usually done in clinics that specialize in genital surgery. The standards of care defined by the Harry Benjamin International Gender Dysphoria Association stipulate that the surgeon should be a board-certified urologist, gynecologist, plastic surgeon, or general surgeon, and that he or she must have undergone supervised training in genital reconstruction.

The morbidity and mortality rates for persons having an orchiectomy as part of gender reassignment surgery are about the same as those for any procedure involving general or epidural anesthesia.

## Alternatives

### Cancer

There is no effective alternative to radical orchiectomy in the treatment of testicular cancer; radiation and chemotherapy are considered follow-up treatments rather than alternatives.

There are, however, several alternatives to orchiectomy in the treatment of prostate cancer:

- watchful waiting
- hormonal therapy (The drugs that are usually given for prostate cancer are either medications that oppose the action of male sex hormones [anti-androgens, usually flutamide or nilutamide] or medications that prevent the production of testosterone [goserelin or leuprolide acetate].)
- radiation treatment
- chemotherapy

### Gender reassignment

The primary alternative to an orchiectomy for gender reassignment is hormonal therapy. Most patients seeking MTF gender reassignment begin taking female

## QUESTIONS TO ASK THE DOCTOR

- How effective is an orchiectomy in preventing a recurrence of my cancer?
- What side effects of this procedure am I most likely to experience?
- How many orchiectomies have you performed?
- Can you recommend a local men's network or support group?

hormones (estrogens) for three to five months minimum before requesting genital surgery. Some persons postpone surgery for a longer period of time, often for financial reasons; others choose to continue on estrogen therapy indefinitely without surgery.

## Orchiopexy

### Definition

Orchiopexy is a procedure in which a surgeon fastens an undescended testicle inside the scrotum, usually with absorbable sutures. It is done most often in male infants or very young children to correct cryptorchidism, which is the medical term for undescended testicles. Orchiopexy is also occasionally performed in adolescents or adults, and may involve one or both testicles. In adults, orchiopexy is most often done to treat testicular torsion, which is a urologic emergency resulting from the testicle's twisting around the spermatic cord and losing its blood supply.

Other names for orchiopexy include orchidopexy, inguinal orchiopexy, repair of undescended testicle, cryptorchidism repair, and testicular torsion repair.

### Purpose

To understand the reasons for performing an orchiopexy in children, it is helpful to have an outline of the normal pattern of development of the testes in a male infant. The gubernaculum is an embryonic cord-like ligament that attaches the testes within the inguinal (groin) region of a male fetus up through the seventh month of pregnancy. Between the 28th and the 35th week of pregnancy, the gubernaculum migrates into the scrotum and creates space for the testes to descend. In normal development, the testes have followed the gubernaculum downward into the scrotum by the time the baby is born. The normal pattern may be interrupted by several possible factors, including inadequate androgen (male sex hormone) secretion, structural abnormalities in the boy's genitals, and defective nerves in the genital region.

Orchiopexy is performed in children for several reasons:

- To minimize the risk of infertility. Adult males with cryptorchidism typically have lower sperm counts and produce sperm of poorer quality than men with normal testicles. The risk of infertility rises

## Orchiopexy

An orchiopexy is used to repair an undescended testicle in childhood. An incision is made into the abdomen, the site of the undescended testicle, and another is made in the scrotum (A). The testis is detached from surrounding tissues (B) and pulled out of the abdominal incision attached to the spermatic cord (C). The testis is then pulled down into the scrotum (D) and stitched into place (E). (Illustration by GGS Information Services. Cengage Learning, Gale.)

with increasing age at the time of orchiopexy and whether both testicles are affected. Men with one undescended testicle have a 40% chance of being infertile; this figure rises to 70% in men with bilateral cryptorchidism.

- To lower the risk of testicular cancer. The incidence of malignant tumors in undescended testes has been estimated to be 48 times the incidence in normal testes. Men with cryptorchidism have a 10% chance of eventually developing testicular cancer.

## KEY TERMS

**Cremasteric reflex**—A reflex in which the cremaster muscle, which covers the testes and the spermatic cord, pulls the testicles back into the scrotum. It is important for a doctor to distinguish between an undescended testicle and a hyperactive cremasteric reflex in small children.

**Cryptorchidism**—A developmental disorder in which one or both testes fail to descend from the abdomen into the scrotum before birth. It is the most common structural abnormality in the male genital tract.

**Ectopic**—Located in an abnormal site or tissue. An ectopic testicle is one that is located in an unusual position outside its normal line of descent into the scrotum.

**Gonadotropins**—Hormones that stimulate the activity of the ovaries in females and testes in males.

**Hernia**—The protrusion of a loop or piece of tissue through an incision or abnormal opening in other tissues.

**Inguinal**—Referring to the groin area.

**Laparoscope**—An instrument that allows a surgeon to look inside the abdominal cavity.

**Non-palpable**—Unable to be detected through the sense of touch. A non-palpable testicle is one that is located in the abdomen or other site where the doctor cannot feel it by pressing gently on the child's body.

**Orchiectomy**—Surgical removal of one or both testicles in a male; also called an orchidectomy.

**Perineum**—The area between the scrotum and the anus.

**Peritoneum**—The smooth, colorless membrane that lines the inner surface of the abdomen.

**Prune belly syndrome (PBS)**—A genetic disorder associated with abnormalities of human chromosomes 18 and 21. Male infants with PBS often have cryptorchidism along with other defects of the genitals and urinary tract. PBS is also known as triad syndrome and Eagle-Barrett syndrome.

**Scrotum**—The pouch of skin on the outside of the male body that holds the testes.

**Spermatic cord**—A tube-like structure that extends from the testicle to the groin area. It contains blood vessels, nerves, and a duct to carry spermatic fluid.

**Testicular torsion**—Twisting of the testicle around the spermatic cord, cutting off the blood supply to the testicle. It is considered a urologic emergency.

**Testis (plural, testes)**—The medical term for a testicle.

**Urology**—The branch of medicine that deals with disorders of the urinary tract in both males and females, and with the genital organs in males.

- To lower the risk of traumatic injury to the testicle. Undescended testicles that remain in the patient's groin area are vulnerable to sports injuries and pressure from car seat belts.
- To prevent the development of an inguinal hernia. An inguinal hernia is a disorder that occurs when a portion of the contents of the abdomen pushes through an abnormal opening in the abdominal wall. It is likely to occur in a male infant with cryptorchidism because a sac known as the processus vaginalis, which connects the scrotum and the abdominal cavity, remains open after birth. In normal development, the processus vaginalis closes shortly after the testes descend into the scrotum. If the sac remains open, a section of the child's intestine can extend into the sac. It may become trapped (incarcerated) in the sac, forming what is called a strangulated hernia. The portion of the intestine that is trapped in the sac may die, which is a medical emergency.
- To prevent testicular torsion in adolescence.
- To maintain the appearance of a normal scrotum. Orchiopexy is considered a necessary procedure for psychological reasons, as boys with only one visible testicle are frequently subjected to teasing and ridicule after they start school.

The primary reason for performing an orchiopexy in an adolescent or adult male is treatment of testicular torsion, rather than cryptorchidism. Testicles that have not descended by the time a boy reaches puberty are usually removed by a complete **orchiectomy**.

## Demographics

### Cryptorchidism

Cryptorchidism is the most common abnormality of the male genital tract, affecting 3–5% of full-term male infants and 30–32% of premature male infants. In most cases, the condition resolves during the first few months after delivery; only 0.8% of infants over three months of age still have undescended testicles.

Because of the potentially serious consequences of cryptorchidism, however, doctors do not advise watchful waiting once the child is over six months old. Undescended testicles rarely come down into the scrotum of their own accord after that age.

Cryptorchidism is a frequent occurrence in prune belly syndrome (PBS) and a few other genetic disorders characterized by structural abnormalities of the genitourinary tract.

No variation in the incidence of cryptorchidism among different racial and ethnic groups has been reported.

### ***Testicular torsion***

Most American males suffering from testicular torsion are below age 30, with the majority between the ages of 12 and 18. The peak ages for an acute episode of testicular torsion are the first year of life and age 14. Testicular torsion occurs on the left side of the body slightly more often than on the right side, about 52% versus 48% of cases.

## **Description**

### ***Cryptorchidism***

Some orchiopexies in children are relatively simple procedures; however, others are complicated by the location of the undescended testicle. In general, an orchiopexy for an undescended testicle that lies in front of the scrotum or just above it is a less complicated operation than one done to treat a non-palpable testicle. The procedure is usually done under **general anesthesia**.

If the undescended testis is in the groin area, the surgeon will make a small incision in the groin and a second small incision in the scrotum. The testis is moved downward from the groin without complete separation from the gubernaculum. It is then placed inside a small pouch created by the surgeon between the skin of the scrotum and a layer of muscle in the scrotum called the dartos muscle. The testicle is held in place with sutures that are eventually absorbed by the body.

The Fowler-Stephens technique is often used when the undescended testicle is located high above the scrotum or in the abdomen. It may be done in two stages scheduled several months apart. In the first stage, the surgeon moves the testicle downward and attaches it temporarily to the inside of the thigh. In the second stage, the testicle is transferred into the scrotum itself and sutured into place.

A third type of orchiopexy is called testicular autotransplantation. The surgeon removes the undescended testicle completely from its present location and re-implants it in the scrotum by reattaching its surrounding tissues and blood vessels to nearby blood vessels. This technique minimizes the risk of an inadequate blood supply to the re-implanted testicle.

### ***Testicular torsion***

An orchiopexy done to treat testicular torsion is usually done under general or epidural anesthesia. The surgeon makes an incision in the patient's scrotum and untwists the spermatic cord. The affected testicle is inspected for signs of necrosis, or tissue **death**. If too much tissue has died due to loss of blood supply, the surgeon will remove the entire testicle. If the tissue appears to be healthy, the surgeon sutures the testicle to the wall of the scrotum and then closes the incision. In most cases, the surgeon will also attach the unaffected testicle to the scrotal wall as a preventive measure.

## **Diagnosis/Preparation**

### ***Cryptorchidism***

The diagnosis of cryptorchidism is usually made when a pediatrician examines the newborn baby, although the condition can occur at any time before the boy reaches puberty. The first stage in diagnosis is an external **physical examination** of the child's genitals. If either testicle does not appear to be in the scrotum, the doctor will palpate, or touch, the groin area and abdomen to determine whether a testicle can be felt in any of those locations. If the testicle can be felt, the doctor will decide on the basis of its location whether it is an undescended testicle, a so-called ectopic testicle, or a retractile testicle. An ectopic testicle is one that has developed in a location outside the normal path of development in the inguinal canal. Ectopic testicles are most often discovered along the inner part of the thigh near the groin, at the base of the penis, or below the scrotum in the perineum (the area between the scrotum and the rectum). A retractile testicle is one that is readily pulled back out of the scrotum by an overly sensitive reflex called the cremasteric reflex; it is not a genuinely undescended testicle. It is important for the doctor to distinguish a retractile testicle from genuine cryptorchidism because retractile testicles do not need surgical treatment. At this point in the diagnostic workup, a general pediatrician will often consult a specialist in pediatric urology.

In about 20% of male infants with cryptorchidism, the missing testicle cannot be felt at all. It is

known as a non-palpable testicle. The child may be given a hormone challenge test to help determine whether the testicle is located in the abdomen or whether it has failed to develop fully. If the testosterone level in the blood rises in response to the test, the doctor knows that there is a testis present somewhere in the child's body. In other cases, the testis has atrophied, or shriveled up due to an inadequate blood supply before birth. If neither testicle can be felt, the child should be examined further for evidence of intersexuality. The doctor may order an **ultrasound** to check for the presence of a uterus, particularly if the child's external genitals are ambiguous in appearance.

Surgery is the next step in searching for a non-palpable testicle. The surgeon may perform either an open inguinal procedure or a laparoscopic approach. In an open inguinal exploration, the surgeon makes an incision in the child's groin; if nothing is found, the incision may be extended into the lower abdomen. In a laparoscopic approach, the surgeon uses an instrument that looks like a small telescope with a light attached in order to see inside the groin or the abdominal cavity through a much smaller incision. If the surgeon is able to find the testicle, he or she may then proceed directly to perform an orchiopexy.

### *Testicular torsion*

Testicular torsion is usually diagnosed in the emergency room. The doctor will usually suspect testicular torsion on the basis of sudden onset of severe pain on one side of the scrotum; it is unusual for pain to develop gradually in this disorder. The patient's history often indicates recent hard physical work, vigorous **exercise**, or trauma to the genital area; however, testicular torsion can also occur without any apparent reason. Other symptoms may include swelling of the scrotum, blood in the semen, nausea and vomiting, pain in the abdomen, and fever. A few patients feel the need to urinate frequently. When the doctor examines the patient's scrotum, the affected testicle is usually enlarged and is painful when the doctor touches it. It usually lies higher in the scrotum than the unaffected testicle and may be lying in a horizontal position.

Since testicular torsion is a medical emergency, most doctors will not risk permanent damage to the testicle by taking the time to perform imaging studies. If the diagnosis is unclear, however, the doctor may order a radionuclide scan or a color Doppler ultrasound to determine whether the blood flow to the testicle has been cut off. The patient will be given a mild pain medication and referred to a urologist for surgery as soon as possible.

## Aftercare

### *Cryptorchidism*

Aftercare in children depends partly on the complexity of the procedure. If the child has an uncomplicated orchiopexy, he can usually go home the same day. If the surgeon had to make an incision in the abdomen to find a non-palpable testicle before performing the orchiopexy, the child may remain in the hospital for two to three days. The doctor will usually prescribe a pain medication for the first few days after the procedure.

After the child returns home, he should not bathe until the day after surgery. In addition, he should not ride a bicycle, climb trees, or do anything else that requires straddling for two to three weeks. An older boy should avoid sports or rough games that might result in injury to the genitals until he has a post-surgical checkup.

Most surgeons will schedule the child for a checkup one or two weeks after the orchiopexy, with a second checkup three months later.

### *Testicular torsion*

Aftercare is similar to that for orchiopexy in a child. The area around the incision should be washed very gently the next day and a clean dressing applied. Medication will be prescribed for postoperative pain. The patient is advised to rest at home for several days after surgery, to remain in bed as much as possible, to drink extra fluids, and to elevate the scrotum on a small pillow to ease the discomfort. Vigorous physical and sexual activity should be avoided until the pain and swelling go away.

## Risks

### *Cryptorchidism*

The risks of orchiopexy in treating cryptorchidism include:

- infection of the incision
- bleeding
- damage to the blood vessels and other structures in the spermatic cord, leading to eventual loss of the testicle
- failure of the testicle to remain in the scrotum (This problem can be repaired by a second operation.)
- difficulty urinating for a few days after surgery

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

A pediatric surgeon or pediatric urologist is the specialist most likely to perform an orchiopexy in an infant or small child. In an adult patient, the procedure is usually performed by a urologist after referral from the patient's primary physician or the emergency care physician.

An orchiopexy can be performed in the surgical unit of a children's hospital or an ambulatory surgical center. Most orchiopexies in adults are performed as outpatient procedures.

### *Testicular torsion*

The risks of orchiopexy as a treatment for testicular torsion include:

- infection of the incision
- bleeding
- loss of blood circulation in the testicle leading to loss of the testicle
- reaction to anesthesia

### Normal results

In a normal orchiopexy, the testicle remains in the scrotum without re-ascending. If the procedure has been successful, there is no damage to the blood vessels supplying the testicle, no loss of fertility, and no recurrence of torsion.

### Morbidity and mortality rates

#### *Cryptorchidism*

Orchiopexy is most likely to be successful in children when the undescended testicle is relatively close to the scrotum. The rate of failure for orchiopexy performed as a treatment for cryptorchidism is 8% if the testicle lies just above the scrotum; 10–20% if the testicle is located in the inguinal canal; and 25% if the testicle lies within the abdomen.

#### *Testicular torsion*

The mortality rate for orchiopexy in adults is very low because almost all patients are young males in good health. The procedure has a 99% rate of success in saving the testicle when the diagnosis is made promptly and treated within six hours. After 12 hours, however,

## QUESTIONS TO ASK THE DOCTOR

- How often have you treated a child for cryptorchidism?
- What are the chances that the treatment will be successful?
- What should I tell my son about the operation?
- Are there likely to be any long-term aftereffects?

the rate of success in saving the testicle drops to 2%. The average rate of testicular atrophy following orchiopexy for testicular torsion is about 27%.

### Alternatives

#### *Cryptorchidism*

Hormonal therapy using gonadotropins to stimulate the production of more testosterone is effective in some children in causing the testes to descend into the scrotum without surgery. This approach, however, is usually successful only with undescended testes that are already close to the scrotum; its rate of success ranges from 10–50%. Undescended testes that are located higher almost never respond to hormonal therapy. In addition, treatment with hormones has several undesirable side effects, including aggressive behavior.

Some surgeons will, however, prescribe hormonal treatment before an orchiopexy in order to increase the size of the undescended testis and make it easier to identify during surgery.

#### *Testicular torsion*

Pain caused by testicular torsion can be relieved temporarily by manual detorsion. To perform this maneuver, the doctor stands at the patient's feet and gently rotates the affected testicle toward the outside of the patient's body in a sidewise direction. Manual detorsion is effective in relieving pain in 30–70% of patients; however, it is not considered an alternative to orchiopexy in preventing a recurrence of the torsion or loss of the testicle.

Rebecca Frey, PhD

## Orthopedic surgery

### Definition

Orthopedic (sometimes spelled orthopaedic) surgery is an operation performed by a medical specialist such as an orthopedist or orthopedic surgeon, who is trained to assess and treat problems that develop in the bones, joints, and ligaments of the human body.

### Purpose

Orthopedic surgery addresses and attempts to correct problems that arise in the skeleton and its attachments, the ligaments and tendons. It may also include some problems of the nervous system, such as those that arise from injury of the spine. These problems can occur at birth, through injury, or as the result of aging. They may be acute, as in an accident or injury, or chronic, as in many problems related to aging.

Orthopedics comes from two Greek words, *ortho*, meaning straight, and *pais*, meaning child. Originally, orthopedic surgeons treated skeletal deformities in children, using braces to straighten the child's bones. With the development of anesthesia and an understanding of the importance of **aseptic technique** in surgery, orthopedic surgeons extended their role to include surgery involving the bones and related nerves and connective tissue.

The terms orthopedic surgeon and orthopedist are used interchangeably today to indicate a medical doctor with special training and certification in orthopedics.

Many orthopedic surgeons maintain a general practice, while some specialize in one particular aspect of orthopedics such as **hand surgery**, joint replacements, or disorders of the spine. Orthopedists treat both acute and chronic disorders. Some orthopedic surgeons specialize in trauma medicine and can be found in emergency rooms and trauma centers, treating injuries. Others find their work overlapping with plastic surgeons, geriatric specialists, pediatricians, or podiatrists (foot care specialists). A rapidly growing area of orthopedics is sports medicine, and many sports medicine doctors are board certified in orthopedic surgery.

### Demographics

The American Academy of Orthopedic Surgeons reports that in January 2008, there are 31,309 members within all categories of orthopedic surgeons in the United States.

## KEY TERMS

**Arthroplasty**—The surgical reconstruction or replacement of a joint.

**Prosthesis**—A synthetic replacement for a missing part of the body such as a knee or a hip.

**Range of motion**—The normal extent of movement (flexion and extension) of a joint.

## Description

The range of treatments provided by orthopedists is extensive. They include procedures such as **traction**, **amputation**, hand reconstruction, **spinal fusion**, and joint replacements. They also treat strains and sprains, broken bones, and dislocations. Some specific procedures performed by orthopedic surgeons are listed as separate entries in this book, including **arthroplasty**, **arthroscopic surgery**, **bone grafting**, **fasciotomy**, **fracture repair**, **kneecap removal**, and traction.

In general, orthopedists are employed by hospitals, medical centers, trauma centers, or free-standing surgical centers where they work closely with a **surgical team**, including an anesthesiologist and surgical nurse. Orthopedic surgery can be performed under general, regional, or **local anesthesia**.

Much of the work of an orthopedic surgeon involves adding foreign material to the body in the form of screws, wires, pins, tongs, and prosthetics to hold damaged bones in their proper alignment or to replace damaged bone or connective tissue. Great improvements have been made in the development of artificial limbs and joints, and in the materials available to repair damage to bones and connective tissue. As developments occur in the fields of metallurgy and plastics, changes will take place in orthopedic surgery that will allow surgeons to more nearly duplicate the natural functions of bones, joints, and ligaments, and to more accurately restore damaged parts to their original ranges of motion.

## Diagnosis/Preparation

Persons are usually referred to an orthopedic surgeon by a primary care physician, emergency room physician, or other doctor. Prior to any surgery, candidates undergo extensive testing to determine appropriate corrective procedures. Tests may include x rays, computed tomography (CT) scans, **magnetic resonance imaging** (MRI), myelograms, diagnostic arthroplasty, and blood tests. The orthopedist will determine the

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

Orthopedic surgery is performed by a physician with specialized training in orthopedic surgery. It is most commonly performed in operating room of a hospital. Very minor procedures such as setting a broken bone may be performed in a professional office or an emergency room of a hospital.

history of the disorder and any treatments that were previously tried. A period of rest to the injured part may be recommended before surgery is undertaken.

Surgical candidates undergo standard blood and urine tests before surgery and, for major procedures, may be given an **electrocardiogram** or other diagnostic tests prior to the operation. Individuals may choose to donate some of their own blood to be held in reserve for their use in major surgery such as **knee replacement**, during which heavy bleeding is common.

## Aftercare

Rehabilitation from orthopedic injuries can require long periods of time. Rehabilitation is usually physically and mentally taxing. Orthopedic surgeons will work closely with physical therapists to ensure that patients receive treatment that will enhance the range of motion and return function to all affected body parts.

## Risks

As with any surgery, there is always the risk of excessive bleeding, infection, and allergic reaction to anesthesia. Risks specifically associated with orthopedic surgery include inflammation at the site where foreign materials (pins, prostheses, or wires) are introduced into the body, infection as the result of surgery, and damage to nerves or to the spinal cord.

## Normal results

Thousands of people have successful orthopedic surgery each year to recover from injuries or to restore lost function. The degree of success in individual recoveries depends on an individual's age and general health, the medical problem being treated, and a person's willingness to comply with rehabilitative therapy after the surgery.

## QUESTIONS TO ASK THE DOCTOR

- What tests will be performed prior to surgery?
- How will the procedure affect daily activities after recovery?
- Where will the surgery be performed?
- What form of anesthesia will be used?
- What will be the resulting appearance and level of function after surgery?
- Is the surgeon board certified by the American Academy of Orthopedic Surgeons?
- How many similar procedures has the surgeon performed?
- What is the surgeon's complication rate?

Abnormal results from orthopedic surgery include persistent pain, swelling, redness, drainage or bleeding in the surgical area, surgical wound infection resulting in slow healing, and incomplete restoration of pre-surgical function.

### Morbidity and mortality rates

Mortality from orthopedic surgical procedures is not common. The most common causes for mortality are adverse reactions to anesthetic agents or drugs used to control pain, post-surgical clot formation in the veins, and post-surgical heart attacks or strokes.

### Alternatives

For the removal of diseased, non-functional, or non-vital tissue, there is no alternative to orthopedic surgery. Alternatives to orthopedic surgery depend on the condition being treated. Medications, acupuncture, or hypnosis are used to relieve pain. Radiation is an occasional alternative for shrinking growths. Chemotherapy may be used to treat bone cancer. Some foreign bodies may remain in the body without harm.

## Otoplasty

### Definition

Otoplasty refers to a group of **plastic surgery** procedures done to correct deformities of or disfiguring injuries to the external ear. It is the only type of plastic surgery that is performed more often in children than adults.

### Purpose

Otoplastic surgery may be done for the following reasons:

- To reconstruct an external ear in children who are born with a partially or completely missing auricle (the visible part of the external ear). This type of birth defect is called microtia; it occurs in such disorders as hemifacial microsomia and Treacher Collins syndrome. Most cases of microtia, however, involve only one ear.
- To correct the appearance of protruding or prominent ears. This procedure is also known as setback otoplasty or pinback otoplasty.
- To correct major disparities in the size or shape of a patient's ears.
- To reshape deformed ears. One congenital type of deformity is known as Stahl's ear, which is characterized by a pointed upper edge produced by the flattening of the ear rim and folding of the cartilage. Stahl's deformity is also known as Vulcan ear or Spock ear because it resembles the ears of the well-known *Star Trek* character.
- To repair or reconstruct the auricle after traumatic injuries or cancer surgery.

Otoplasty is considered reconstructive rather than **cosmetic surgery**. Consequently, it is often covered by health insurance. People who are considering

During an otoplasty, an incision is made in the back of the ear, exposing cartilage (A). Permanent sutures in the cartilage pull the ear back closer to the skull (B). The incision is closed (C), and dressings are applied (D). (Illustration by GGS Information Services. Cengage Learning, Gale.)

otoplasty for themselves or their children should check with their insurance carrier about coverage. The average surgeon's fee for an otoplasty in the United States in 2001 was \$3,114.

Otoplasty is not done to correct hearing difficulties related to the structures of the middle and inner ear. Hearing problems are treated surgically by otolaryngologists (physicians who specialize in ear, nose, and throat procedures).

### Demographics

Statistics for congenital deformities of the external ear are difficult to obtain because the causes are so diverse. Such genetic disorders as Treacher Collins syndrome and hemifacial microsomia affect between one in 3,500 and one in 10,000 children. In addition, microtia has been associated with certain medications taken during pregnancy—particularly anticonvulsants, which are drugs given to treat epilepsy, and isotretinoin, a drug prescribed for severe acne.

Stahl's deformity is found more often among Asian Americans than among Caucasian or African Americans. As of 2003, it is thought to be a hereditary disorder.

Setback or pinback otoplasty is the most frequently performed procedure for reconstruction of prominent or protruding ears. According to the American Society of Plastic Surgeons, 30,137 setback otoplasties were performed in the United States in 2006. There are no exact statistics on the incidence of protruding ears in the general population, although about 8% of patients treated for this deformity have a family history of it. Large or protruding ears appear to be equally common in males and females; however, it is easier for girls and women to avoid social discomfort by styling their hair to cover their ears. This factor may explain why a slight majority (53%) of setback otoplasties is done on boys. Although most setback otoplasties are performed in children between the ages of four and 14, the second largest group of patients in this category is women in their 20s and 30s.

The most common cause of trauma requiring otoplasty is human and animal bites. Although exact figures are not known because many bite cases are not reported, a large percentage of dog and human bites cause wounds on the head and neck. With regard to human bites, the single most common injury requiring medical treatment is auricular avulsion, or tearing of the external ear. In the United States, 93% of patients treated for ear injuries caused by human bites are males between the ages of 15 and 25. Most cases of auricular avulsion in children, however, are

## KEY TERMS

**Auricle**—The portion of the external ear that is not contained inside the head. It is also called the pinna.

**Avulsion**—A type of injury caused by ripping or tearing. Most ear injuries requiring otoplasty are avulsion injuries.

**Concha**—The hollow shell-shaped portion of the external ear.

**Congenital**—Present at the time of birth.

**Ear molding**—A non-surgical method for treating ear deformities shortly after birth with the application of a mold held in place by tape and surgical glue.

**Hematoma**—A localized collection of blood in an organ or tissue due to broken blood vessels.

**Hemifacial microsomia (HFM)**—A term used to describe a group of complex birth defects characterized by underdevelopment of one side of the face.

**Microtia**—The partial or complete absence of the auricle of the ear.

**Pinna**—Another name for the auricle; the visible portion of the external ear.

**Setback otoplasty**—A surgical procedure done to reduce the size or improve the appearance of large or protruding ears; it is also known as pinback otoplasty.

**Stahl's deformity**—A congenital deformity of the ear characterized by a flattened rim and pointed upper edge caused by a fold in the cartilage; it is also known as Vulcan ear or Spock ear.

**Treacher Collins syndrome**—A disorder that affects facial development and hearing, thought to be caused by a gene mutation on human chromosome 5. Treacher Collins syndrome is sometimes called mandibulofacial dysostosis.

caused by dog bites, which are likely to cause crushing as well as tearing of the tissues.

### Description

Otoplasty in children is performed under **general anesthesia**; in adults, it may be done under either general anesthesia or **local anesthesia** with sedation. Most otoplasties take about two to three hours to complete. Many plastic surgeons prefer to use absorbable sutures when performing an otoplasty in order to minimize the risk of disturbing the shape of the ear by removing **stitches** later.

### *Otoplasty for microtia*

Otoplasty for microtia requires a series of three or four separate operations. In the first operation, a piece of cartilage is removed from the child's rib cage on the side opposite the affected ear, so that the surgeon can use the natural curve of the cartilage in fashioning the new ear. The surgeon works from a template derived from photographs and computer models when he or she carves the cartilage into the desired shape. The cartilage is then carefully positioned under the skin on the side of the face. The skin will shape itself to fit the cartilage framework of the new ear. The second and third operations are done to shape the ear lobe and to raise the new ear into its final position.

### *Otoplasty for protruding ears*

There is no universally accepted single technique for performing a setback otoplasty. Variations in the procedure are due partly to the different causes of ear protrusion. The patient's ear may have a large concha (the shell-like hollow of the external ear); the angle of the fold in the ear cartilage may cause the ear to protrude; or the ear lobe may be unusually large.

After the patient has been anesthetized, the surgeon makes an incision behind the ear in the fold of skin where the ear meets the head. In one technique, the surgeon exposes the ear cartilage beneath the skin and reshapes it or removes a small piece. The cartilage is bent back toward the head and secured in place with non-removable sutures. Removal of cartilage is sometimes referred to as a conchal resection.

Another procedure for protruding ears involves the removal of skin and suturing the cartilage back on itself. This technique reshapes the ear without the need to remove cartilage; it is sometimes called a cartilage-sparing otoplasty.

After the surgeon has finished reshaping the ear and carefully drying the area, the incision is closed. The surgeon covers the ear with a cotton dressing moistened with mineral oil or other soft dressing.

## Diagnosis/Preparation

### *Congenital abnormalities of the ear*

Diagnosis of microtia is made by the obstetrician or pediatrician at the time of the child's birth. The diagnosis of prominent or protruding ears, however, is somewhat more complex because the deformity is a matter of shape and proportion rather than the absence or major malformation of a body part. The head of a newborn infant is larger in proportion to its body than is the case in adults, and as a result, the

shape of the ears may not concern the parents until the child is two to three years old.

Otoplasty to correct microtia is usually started when the child is at least five years old. The surgeon must remove a portion of rib cartilage in order to construct a framework for the missing ear, and children younger than five may not have enough cartilage. In addition, it is easier for the surgeon to use the child's normal ear as a model for the size and shape of the reconstructed ear when the child is five to seven years old. Otoplasty for microtia is preceded by consultations between the surgeon and the child's parents. Following the diagnosis, a comprehensive treatment plan is made that includes long-term psychosocial as well as surgical follow-up. The reconstruction of a missing ear must be done in several stages because the surgeon must allow for changes in the proportions of the child's face and skull as he or she matures as well as attempt to make the new ear look as normal as possible.

There continues to be some debate among plastic surgeons concerning the best age for performing a setback otoplasty. Many recommend the operation when the child is between five and seven years old. One reason is that the human ear has attained 85–90% of its adult size by this age, and therefore the surgeon can estimate the final size and shape of the ear with considerable accuracy. In addition, the cartilage in the ear is still relatively soft and easier for the surgeon to reshape. Another reason for performing an otoplasty in children in the early elementary school years is psychological; name-calling and teasing by peers can be emotionally destructive for children in this age bracket. On the other hand, some surgeons have reported performing setback otoplasties on children as young as nine months with no disturbances in the growth of the ear or recurrence of the problem.

Preparation for otoplasty in children should include an assessment of the child's feelings about the procedure. Some surgeons consider opposition on the child's part to be a contraindication for surgery, as well as unrealistic expectations on the part of the parents. In general, a positive attitude is associated with faster recovery and better overall results.

Preparation for otoplasty in adults includes a **physical examination** and standard blood tests. Patients are usually advised to discontinue taking **aspirin** and any other medications that thin the blood for two weeks prior to surgery. Plastic surgeons strongly urge adult patients to quit smoking before the surgery, because smoking delays and complicates the healing process. Adult patients are also asked to shower and shampoo

their hair thoroughly on the morning of the procedure. Men should have a haircut or trim a day or two before surgery; women should braid or pin their hair close to the head.

### *Trauma*

Avulsion injuries caused by bites, thermal or chemical burns resulting from industrial accidents, and other traumatic injuries of the auricle are diagnosed by emergency physicians.

Plastic surgery for traumatic injuries of the auricle is preceded by thorough cleansing of the wound and **debridement** of damaged tissue. It is important to treat ear injuries promptly because the ears are not well supplied with blood vessels. This characteristic makes it easier for infection to develop in parts of the auricle where the skin has been torn open or crushed. In some cases, plastic surgery is postponed for a few days and the patient is given oral penicillin to prevent infection.

### *Aftercare*

After an otoplasty, the patient's head is wrapped with a turban-type bandage that is worn for four to five days following surgery. The patient is instructed to wear a ski-type headband over the ears continuously for about a month after the turban is removed, and then at night for an additional two months. Warm compresses should be applied to the ears two to three times a day for two weeks after the turban is removed.

Patients should follow the surgeon's instructions about washing their hair, and avoid holding hot-air blow dryers too close to the ear.

Patients should also avoid contact sports for at least three months after otoplasty. An anti-inflammatory medication (Kenalog) can be applied to the ear in the event of abnormal scar formation.

### *Risks*

Some risks associated with otoplasties are common to all operations performed under general anesthesia. They include bleeding or infection of the incision; numbness or loss of feeling in the area around the incision; and a reaction to the anesthesia.

Specific risks associated with otoplasties include the following:

- Formation of abnormal scar tissue. This complication can usually be corrected later; plastic surgeons advise waiting at least six months for revision surgery.
- Hematoma, which is a collection of blood within a body organ or tissue caused by leakage from broken

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

Otoplasties for microtia and prominent or deformed ears are specialized procedures performed only by qualified plastic surgeons. Plastic surgeons are doctors who have completed three years of general surgical training, followed by two to three years of specialized training in plastic surgery. There are, however, relatively few plastic surgeons who perform otoplasties for microtia.

Ear molding as an alternative to surgery is performed by a plastic surgeon as an outpatient or office procedure.

Traumatic injuries of the external ear are treated initially by an emergency physician, trauma surgeon, or plastic surgeon; in most cases, an otolaryngologist is consulted to determine whether the inner structures of the ear have also been injured. Revision plastic surgery may be performed later to remove scar tissue.

blood vessels. In the case of the ear, a hematoma can damage the results of plastic surgery because it creates tension and pressure that distort the final shape of the ear. Careful drying of the ear at the end of the procedure and application of a pressure bandage can reduce the risk of a hematoma. In the event that one develops, it is treated by reopening the incision and draining the collected blood.

- Distortion of the shape of the ear caused by over-correction of deformed features.
- Reappearance of ear protrusion (in setback otoplasty). This complication is most likely to occur in the first six months after surgery.

### *Normal results*

The normal result of an otoplasty is a reconstructed or reshaped ear that resembles a normal ear (or the patient's other ear) more closely. In a setback otoplasty, the normal result is an ear that lies closer to the patient's head without an overcorrected, "pinned-back" look.

### *Morbidity and mortality rates*

The mortality rate in otoplasty is extremely low and is almost always associated with anesthesia reactions. The most common complication reported is

## QUESTIONS TO ASK THE DOCTOR

- How long will it take for the ear to assume its final shape?
- How much change in the shape of the ear can be reasonably expected?
- Would my child benefit from ear molding rather than surgery?
- How many otoplasties have you performed?

asymmetrical ears (18.4%), followed by skin irritation (9.8%); increased sensitivity to cold (7.5%); soreness when the ear is touched (5.7%); abnormal shape to the ear (4.4%); loss of feeling in the ear (3.9%); bleeding (2.6%); and hematoma (0.4%).

### Alternatives

Some ear deformities in children, including protruding ears and Stahl's deformity, can be treated with ear molding in the early weeks of life, when the cartilage in the ear can be reshaped by the application of splints and Steri-Strips. One technique involves making a mold in the shape desired for the child's ear from dental compound and attaching it to the ear with methylmethacrylate **glue**. The ear and the mold are held in place with surgical tape and covered with a tubular bandage or ear wrap for reinforcement. The mold and tape must be worn constantly for six weeks, with a change of dressing every two weeks. Ear molding is reported to be about 85% effective when it is started within six weeks after the baby's birth. It costs less than surgery—about \$600—and is considerably less painful. The chief disadvantage of ear molding is its ineffectiveness in treating ear deformities characterized by the absence of skin and cartilage rather than distorted shape.

There are no effective alternatives to otoplasty in treating ear deformities or injuries in adults; however, some plastic surgeons use custom-made silicone molds to help maintain the position of the ears in adult patients for several weeks after surgery.

# Outpatient surgery

## Definition

Outpatient surgery, also referred to as ambulatory surgery, is defined by the American Hospital Association (AHA) as “a surgical operation, whether major or minor, performed on patients who do not remain in the hospital overnight.” Outpatient surgery may be performed in inpatient operating suites, outpatient surgery suites, or procedure rooms within an outpatient care facility. Patients may go home after being released following the procedure and time spent in the **recovery room**.

## Purpose

Mounting pressure to keep hospitalization costs down and improved technology have increased the frequency of outpatient surgery, with shorter medical procedure duration, fewer complications, and lower cost. As of 2006, about 53% of all surgical procedures in the United States are performed on an outpatient basis.

According to the Agency for Healthcare Research and Quality, about 90% of outpatient surgeries in the United States are performed to treat an illness or disorder; the remaining 10% are diagnostic procedures.

## Description

Due to improved pain control, advanced medical techniques—including those that reduce recovery time—and cost-cutting considerations, more and more surgeries are being performed on an outpatient basis. Surgeries suited to a nonhospital setting generally are those with a low percentage of postoperative complications, which would require serious attention by a physician or nurse. Outpatient surgery continues to mushroom: in 1984, roughly 400,000 outpatient surgeries were performed; by 2000, the number had risen to 8.3 million; and from 1993 to 2001, the number of freestanding **ambulatory surgery centers** in the United States increased by 150%. A 2002 study reported that 65% of all surgical procedures did not involve a hospital stay; this proportion is expected to increase to 75% by 2015. These statistics also reflect the fact that many patients (especially children) prefer to recover at home or in a familiar setting.

With increased technological advances in instruments such as the arthroscope and laparoscope, more physicians are performing surgery in their offices or in other outpatient settings, primarily ambulatory clinics and surgical centers, or surgicenters. Among the most

## KEY TERMS

**Ambulatory surgery**—Surgery done on an outpatient basis; the patient goes home the same day.

**Ambulatory surgery center**—An outpatient facility with at least two operating rooms, either connected or not connected to a hospital.

**Outpatient procedures**—Surgeries that are performed on an outpatient basis, involving less recovery time and fewer expected complications.

frequently performed outpatient surgeries are tonsillectomies, arthroscopy, **cosmetic surgery**, removal of cataracts, gynecological, urological and orthopedic procedures, wound and hernia repairs, and gallbladder removals. Even such procedures as microscopically controlled surgery under **local anesthesia** for skin cancer have been recommended on an outpatient basis.

## Preparation

While many outpatient surgeries are covered by insurance plans, many are not. Candidates for such surgeries should check in advance with their insurance carrier concerning whether their procedures are covered on an outpatient basis. **Medicare** and **Medicaid** patients should also check whether these programs will cover the cost of their surgeries.

Preparing for outpatient surgery varies, of course, with the surgical procedure to be performed. There are, however, guidelines common to most outpatient surgeries. Patients should be in good health before undergoing ambulatory surgery. Colds, fever, chills, or flu symptoms are all reasons to postpone a procedure, and surgical candidates should notify their primary health care physicians if such conditions exist.

Patients should check with their physician for all information covering preparation for outpatient procedures. A near-universal requirement is to have a family member or friend take charge of delivering the patient to surgery, either to wait there or to arrive in time to pick up the patient on release from recovery. The evening before, a light meal is recommended to preoperative patients, with no alcohol taken for a full day before surgery. Nothing is to be taken by mouth after midnight of the day preceding surgery. Smokers should stop or cut back on smoking prior to surgery. Loose-fitting clothing is recommended, and patients should bring along enough money to cover postoperative prescription drugs.

This same information applies if the outpatient is a child. If children are permitted clear liquids on the day of outpatient surgery, parents will be told when the child must stop taking them. Surgery will be cancelled or delayed if these requirements are not met.

## Results

The benefits of outpatient surgery include lower medical costs, tighter scheduling—because patients are not subject to the potential delays encountered in hospital operating rooms—and what many patients would consider a less stressful environment than a hospital setting. Recovery time spent in one's own home, either with familiar caregivers or home nurses, is a choice many postoperative patients prefer to recuperation in a hospital.

Complications related to surgery occur less than 1% of the time in outpatient settings. However, in terms of patient safety, nonhospital settings are not as closely regulated as are hospitals, so patients should inquire about potential risks concerning outpatient surgery that arise in ambulatory clinics, surgical centers, and physicians' offices. There are guidelines for surgery in outpatient settings, but oversight and enforcement may vary. Patients may wish to find out whether their outpatient center is licensed or certified as a medical facility or is accredited in the states that require this. The latter may be accomplished by contacting the Joint Commission (formerly the Joint Commission for Accreditation of Healthcare Organizations).

Among problems encountered during outpatient surgery are those concerning anesthesia administration, infection, bleeding that calls for a **transfusion**, and respiratory and resuscitation events. Some patients are at higher risk than others of requiring inpatient admission after an outpatient procedure. These include patients over the age of 65; operations lasting longer than 120 minutes; the need for **general anesthesia**; and patients with heart problems, cancer, or vascular disease.

## Oxygen therapy

### Definition

Oxygen may be classified as an element, a gas, and a drug. Oxygen therapy is the administration of oxygen at concentrations greater than that in room air to treat or prevent hypoxemia (not enough oxygen in the blood). Oxygen delivery systems are classified as stationary, portable, or ambulatory. Oxygen can be administered by nasal cannula, mask, and tent. Hyperbaric oxygen therapy involves placing the patient in an airtight chamber with oxygen under pressure.

### Purpose

The body is constantly taking in oxygen and releasing carbon dioxide. If this process is inadequate, oxygen levels in the blood decrease, and the patient may need supplemental oxygen. Oxygen therapy is a

## KEY TERMS

**Arterial blood gas test**—A blood test that measures oxygen and carbon dioxide in the blood.

**Atelectasis**—Partial or complete collapse of the lung, usually due to a blockage of the air passages with fluid, mucus or infection.

**Breathing rate**—The number of breaths per minute.

**Cannula**—Also called nasal cannula. A small, lightweight plastic tube with two hollow prongs that fit just inside the nose. Nasal cannulas are used to supply supplemental oxygen through the nose.

**Cyanosis**—Blue, gray, or dark purple discoloration of the skin caused by a deficiency of oxygen.

**Ductus arteriosus**—A fetal blood vessel that connects the aorta and pulmonary artery.

**Flow meter**—Device for measuring the rate of a gas (especially oxygen) or liquid.

**Hypoxemia**—Oxygen deficiency, defined as an oxygen level less than 60 mm Hg or arterial oxygen saturation of less than 90%. Different values are used for infants and patients with certain lung diseases.

**Oxygenation**—Saturation with oxygen.

**Peak expiratory flow rate**—A test used to measure how fast air can be exhaled from the lungs.

**Pulmonary function tests**—A series of tests that measure how well air is moving in and out of the lungs and carrying oxygen to the bloodstream.

**Pulmonary rehabilitation**—A program that helps patients learn how to breathe easier and improve their quality of life. Pulmonary rehabilitation includes treatment, exercise training, education, and counseling.

**Pulmonologist**—A physician who specializes in caring for people with lung diseases and breathing problems.

**Pulse oximetry**—A non-invasive test in which a device that clips onto the finger measures the oxygen level in the blood.

**Residual volume**—The volume of air remaining in the lungs, measured after a maximum expiration.

**Respiratory failure**—The sudden inability of the lungs to provide normal oxygen delivery or normal carbon dioxide removal.

**Respiratory therapist**—A health care professional who specializes in assessing, treating, and educating people with lung diseases.

**Total lung capacity test**—A test that measures the amount of air in the lungs after a person has breathed in as much as possible.

**Vital capacity**—Maximal breathing capacity; the amount of air that can be expired after a maximum inspiration.

key treatment in respiratory care. The purpose is to increase oxygen saturation in tissues where the saturation levels are too low due to illness or injury. Breathing prescribed oxygen increases the amount of oxygen in the blood, reduces the extra work of the heart, and decreases shortness of breath. Oxygen therapy is frequently ordered in the **home care** setting, as well as in acute (urgent) care facilities.

Some of the conditions oxygen therapy is used to treat include:

- documented hypoxemia
- severe respiratory distress (e.g., acute asthma or pneumonia)
- severe trauma
- chronic obstructive pulmonary disease (COPD, including chronic bronchitis, emphysema, and chronic asthma)
- pulmonary hypertension
- cor pulmonale

- acute myocardial infarction (heart attack)
- short-term therapy, such as postanesthesia recovery

Oxygen may also be used to treat chronic lung disease patients during **exercise**.

Hyperbaric oxygen therapy is used to treat the following conditions:

- gas gangrene
- decompression sickness
- air embolism
- smoke inhalation
- carbon monoxide poisoning
- cerebral hypoxic event

Helium-oxygen therapy is a treatment that may be used for patients with severe airway obstruction. The combination of helium and oxygen, known as heliox, reduces the density of the delivered gas, and has been shown to reduce the effort of breathing and improve ventilation when an airway obstruction is present.

This type of treatment may be used in an emergency room for patients with acute, severe asthma.

## Description

### *Oxygen delivery (other than mechanical ventilators and hyperbaric chambers)*

In the hospital, oxygen is supplied to each patient room via an outlet in the wall. Oxygen is delivered from a central source through a pipeline in the facility. A flow meter attached to the wall outlet accesses the oxygen. A valve regulates the oxygen flow, and attachments may be connected to provide moisture. In the home, the oxygen source is usually a canister or air compressor. Whether in home or hospital, plastic tubing connects the oxygen source to the patient.

Oxygen is most commonly delivered to the patient via a nasal cannula or mask attached to the tubing. The nasal cannula is usually the delivery device of choice since it is well tolerated and doesn't interfere with the patient's ability to communicate, eat, or drink. The concentration of oxygen inhaled depends upon the prescribed flow rate and the ventilatory minute volume (MV).

Another delivery option is transtracheal oxygen therapy, which involves a small flexible catheter inserted in the trachea or windpipe through a tracheostomy tube. In this method, the oxygen bypasses the mouth, nose, and throat, and a humidifier is required at flow rates of 1 liter (2.1 pt) per minute and above. Other oxygen delivery methods include tents and specialized infant oxygen delivery systems.

**TYPES OF OXYGEN DELIVERY SYSTEMS.** The types of oxygen delivery systems include:

- Compressed oxygen—oxygen that is stored as a gas in a tank. A flow meter and regulator are attached to the oxygen tank to adjust oxygen flow. Tanks vary in size from very large to smaller, portable tanks. This system is generally prescribed when oxygen is not needed constantly (e.g., when it is only needed when performing physical activity).
- Liquid oxygen—oxygen that is stored in a large stationary tank that stays in the home. A portable tank is available that can be filled from the stationary tank for trips outside the home. Oxygen is liquid at very cold temperatures. When warmed, liquid oxygen changes to a gas for delivery to the patient.
- Oxygen concentrator—electric oxygen delivery system approximately the size of a large suitcase. The concentrator extracts some of the air from the room, separates the oxygen, and delivers it to the patient via a nasal cannula. A cylinder of oxygen is provided as a

backup in the event of a power failure, and a portable tank is available for trips outside the home. This system is generally prescribed for patients who require constant supplemental oxygen or who must use it when sleeping.

- Oxygen conserving device, such as a demand inspiratory flow system or pulsed-dose oxygen delivery system—uses a sensor to detect when inspiration (inhalation) begins. Oxygen is delivered only upon inspiration, thereby conserving oxygen during exhalation. These systems can be used with either compressed or liquid oxygen systems, but are not appropriate for all patients.

## Preparation

A physician's order is required for oxygen therapy, except in emergency use. The need for supplemental oxygen is determined by inadequate oxygen saturation, indicated in blood gas measurements, pulse oximetry, or clinical observations. The physician will prescribe the specific amount of oxygen needed by the patient. Some patients require supplemental oxygen 24 hours a day, while others may only need treatments during exercise or sleep. No special patient preparation is required to administer oxygen therapy.

### *Patient education*

**SELECTING AN OXYGEN SYSTEM.** A health care provider will meet with the patient to discuss the oxygen systems available. A system recommendation will be made, based on the patient's overall condition and personal needs, as well as the system's ease of use, reliability, cost, range of oxygen delivery, and features. The health care provider can give the patient a list of medical supply companies that stock home oxygen equipment and supplies. The patient can meet with home care representatives from these companies to evaluate the product lines that best fit his or her needs. Patients in the home setting are directed to notify the vendors when replacement oxygen supplies are needed.

**OXYGEN SAFETY.** Patients will receive instructions about the safe use of oxygen in the home. Patients must be advised not to change the flow rate of oxygen unless directed to do so by the physician.

Oxygen supports combustion, therefore no open flame or combustible products should be permitted when oxygen is in use. These include petroleum jelly, oils, and aerosol sprays. A spark from a cigarette, electric razor, or other electrical device could easily ignite oxygen-saturated hair or bedclothes around the patient. Explosion-proof plugs should be used for vaporizers and humidifier attachments. The patient

should be sure to have a functioning smoke detector and fire extinguisher in the home at all times.

Care must be taken with oxygen equipment used in the home or hospital. The oxygen system should be kept clean and dust-free. Cylinders should be kept in carts, or have collars for safe storage. If not stored in a cart, smaller canisters may be laid on the floor. Knocking cylinders together can cause sparks, so bumping them should be avoided. In the home, the oxygen source must be placed at least 6 ft (1.8 m) away from flames or other sources of ignition, such as a lit cigarette. Oxygen tanks should be kept in a well-ventilated area. Oxygen tanks should not be kept in the trunk of a car. “No Smoking—Oxygen in Use” signs should be used to warn visitors not to smoke near the patient.

Special care must be given when administering oxygen to premature infants because of the danger of high oxygen levels causing retinopathy of prematurity, or contributing to the construction of ductus arteriosus. PaO<sub>2</sub> (partial pressure of oxygen) levels greater than 80 mm Hg should be avoided.

Patients who are undergoing a laser **bronchoscopy** should receive concurrent administration of supplemental oxygen to avoid burns to the trachea.

#### *Insurance clearance*

The patient should check with his or her insurance provider to determine if the treatment is covered and what out-of-pocket expenses may be incurred. Oxygen therapy is usually fully or partially covered by most insurance plans, including **Medicare**, when prescribed according to specific guidelines. Usually test results indicating the medical necessity of the supplemental oxygen are needed before insurance clearance is granted.

#### *Travel guidelines*

Traveling with oxygen requires advanced planning. The patient needs to obtain a letter from his or her health care provider that verifies all medications, including oxygen. In addition, a copy of the patient's oxygen prescription must be shown to travel personnel. Home health care companies can help the patient make travel plans, and can arrange for oxygen when the patient arrives at his or her destination. Patients cannot bring or use their own oxygen tanks on an airplane; therefore the patient must leave his or her portable oxygen tank at the airport before boarding. Oxygen suppliers can pick up the oxygen unit from the airport if necessary, or a family member can take it home.

### Aftercare

Once oxygen therapy is initiated, periodic assessment and documentation of oxygen saturation levels is required. Follow-up monitoring includes blood gas measurements and pulse oximetry tests. If the patient is using a mask or a cannula, gauze can be tucked under the tubing to prevent irritation of the cheeks or the skin behind the ears. Water-based lubricants can be used to relieve dryness of the lips and nostrils.

### Risks

Oxygen is not addictive and causes no side effects when used as prescribed. Complications from oxygen therapy used in appropriate situations are infrequent. Respiratory depression, oxygen toxicity, and absorption atelectasis are the most serious complications of oxygen overuse.

A physician should be notified and emergency services may be required if the following symptoms develop:

- frequent headaches
- anxiety
- cyanotic (blue) lips or fingernails
- drowsiness
- confusion
- restlessness
- slow, shallow, difficult, or irregular breathing

Oxygen delivery equipment may present other problems. Perforation of the nasal septum as a result of using a nasal cannula and non-humidified oxygen has been reported. In addition, bacterial contamination of nebulizer and humidification systems can occur, possibly leading to the spread of pneumonia. High-flow systems that employ heated humidifiers and aerosol generators, especially when used by patients with artificial airways, also pose a risk of infection.

### Normal results

A normal result is a patient that demonstrates adequate oxygenation through pulse oximetry, blood gas tests, and clinical observation. Signs and symptoms of inadequate oxygenation include cyanosis, drowsiness, confusion, restlessness, anxiety, or slow, shallow, difficult, or irregular breathing. Patients with obstructive airway disease may exhibit “aerophagia” (air hunger) as they work to pull air into the lungs. In cases of carbon monoxide inhalation, the oxygen saturation can be falsely elevated.

Pacemaker implantation see **Pacemakers**

## Pacemakers

### Definition

A pacemaker is a surgically implanted electronic device that regulates a cardiac arrhythmia.

Pacemakers are most frequently prescribed when the heartbeat decreases under 60 beats per minute at rest (severe symptomatic bradycardia). They are also used in some cases to slow a fast heart rate over 120 beats per minute at rest (tachycardia).

### Demographics

The population for pacemaker implant is not limited by age, sex, or race. Over 100,000 pacemakers are implanted per year in the United States. The occurrence is more frequent in the elderly with over 85% of implants received by those over age 65. A history of myocardial infarction (heart attack), congenital defect, or cardiac transplant also increases the likelihood of pacemaker implant.

### Description

Approximately 500,000 Americans have an implantable permanent pacemaker device. A pacemaker implantation is performed under **local anesthesia** in a hospital by a surgeon assisted by a cardiologist. An insulated wire called a lead is inserted into an incision above the collarbone and guided through a large vein into the chambers of the heart. Depending on the configuration of the pacemaker and the clinical needs of the patient, as many as three leads may be used in a pacing system. Current pacemakers have a double, or bipolar, electrode attached to the end of each lead. The electrodes deliver an electrical charge to the heart to regulate

heartbeat. They are positioned on the areas of the heart that require stimulation. The leads are then attached to the pacemaker device, which is implanted under the skin of the patient's chest.

Patients undergoing surgical pacemaker implantation usually stay in the hospital overnight. Once the procedure is complete, the patient's **vital signs** are monitored and a **chest x ray** is taken to ensure that the pacemaker and leads are properly positioned.

Modern pacemakers have sophisticated programming capabilities and are extremely compact. The smallest weigh less than 13 grams (under half an ounce) and are the size of two stacked silver dollars. The actual pacing device contains a pulse generator, circuitry programmed to monitor heart rate and deliver stimulation, and a lithium iodide battery. Battery life typically ranges from seven to 15 years, depending on the number of leads the pacemaker is configured with and how much energy the pacemaker uses. When a new battery is required, the unit can be exchanged in a simple outpatient procedure.

A temporary pacing system is sometimes recommended for patients who are experiencing irregular heartbeats as a result of a recent heart attack or other acute medical condition. The implantation procedure for the pacemaker leads is similar to that for a permanent pacing system, but the actual pacemaker unit housing the pulse generator remains outside the patient's body. Temporary pacing systems may be replaced with a permanent device at a later date.

### Diagnosis/Preparation

Patients being considered for pacemaker implantation will undergo a full battery of cardiac tests, including an **electrocardiogram** (ECG), electrophysiological study, or both, to fully evaluate the bradycardia or tachycardia.

The symptoms of fatigue and lightheadedness that are characteristic of bradycardia can also be caused by

## KEY TERMS

**Electrocardiogram (ECG)**—A recording of the electrical activity of the heart. An ECG uses externally attached electrodes to detect the electrical signals of the heart.

**Electrophysiological study**—A test that monitors the electrical activity of the heart in order to diagnose arrhythmia. An electrophysiological study measures electrical signals through a cardiac catheter that is inserted into an artery in the leg and guided up into the atrium and ventricle of the heart.

**Embolism**—A blood clot, air bubble, or clot of foreign material that blocks the flow of blood in an artery. When an embolism blocks the blood supply to a tissue or organ, the tissue the artery feeds dies (infarction). Without immediate and appropriate treatment, an embolism can be fatal.

**Magnetic resonance imaging (MRI)**—An imaging technique that uses a large circular magnet and radio waves to generate signals from atoms in the body. These signals are used to construct images of internal structures.

a number of other medical conditions, including anemia. Certain prescription medications can also slow the heart rate. A doctor should take a complete medical history and perform a full physical work-up to rule out all non-cardiac causes of bradycardia.

Patients are advised to abstain from eating six to eight hours before the surgical procedure. The patient is usually given a sedative to help him or her relax for the procedure. An intravenous (IV) line will also be inserted into a vein in the patient's arm before the procedure begins in case medication or blood products are required during the insertion.

### Aftercare

After an implant without complications the patient can expect a hospital stay of one to five post-procedure days. Pacemaker patients should schedule a follow-up visit with their cardiologist approximately six weeks after the surgery. During this visit, the doctor will make any necessary adjustments to the settings of the pacemaker. Pacemakers are programmed externally with a handheld electromagnetic device. Pacemaker batteries must be checked regularly. Some pacing systems allow patients to monitor battery life through a special telephone monitoring service that can read pacemaker signals.

## WHO PERFORMS THIS PROCEDURE AND WHERE IS IT PERFORMED?

Pacemaker implants are performed by a cardiologist who has completed medical school and an additional internship and residency program. Additional training as an electrophysiologist may be acquired by the physician during the residency program. Specific training by the pacemaker manufacturer may also be acquired. Hospitals performing these procedures have access to cardiac catheterization facilities or operating rooms equipped with portable fluoroscopy units.

Patients with cardiac pacemakers should not undergo a **magnetic resonance imaging (MRI)** procedure. Devices that emit electromagnetic waves (including magnets) may alter pacemaker programming or functioning. A 1997 study found that cellular phones often interfere with pacemaker programming and cause irregular heart rhythm. However, advances in pacemaker design and materials have greatly reduced the risk of pacemaker interference from electromagnetic fields.

### Risks

Because pacemaker implantation is an invasive surgical procedure, internal bleeding, infection, hemorrhage, and embolism are all possible complications. Infection is more common in patients with temporary pacing systems. Antibiotic therapy given as a precautionary measure can reduce the risk of pacemaker infection. If infection does occur, the entire pacing system may have to be removed.

The placing of the leads and electrodes during the implantation procedure also presents certain risks for the patient. The lead or electrode could perforate the heart or cause scarring or other damage. The electrodes can also cause involuntary stimulation of nearby skeletal muscles.

A complication known as pacemaker syndrome develops in approximately 7% of pacemaker patients with single-chamber pacing systems. The syndrome is characterized by the low blood pressure and dizziness that are symptomatic of bradycardia. It can usually be corrected by the implantation of a dual-chamber pacing system.

## QUESTIONS TO ASK THE DOCTOR

- How many pacemaker implants has the physician performed?
- What type of pacemaker will be implanted, univentricular or biventricular, and how many of the specific procedure has the physician performed?
- How long will the expected hospital stay be?
- What precautions should be taken in the weeks following discharge from the hospital?
- What precautions will need to be taken in day to day activities following pacemaker implant?
- When can normal daily, such as driving, exercise and work, activities be initiated?
- What will indicate that the pacemaker is failing and when should emergency care be sought?
- How long will the battery function and when should treatment to replace the device be sought?
- Is there special documentation I will need for air travel during security screenings?
- Will there be notification of manufacturer recalls?

### Normal results

Pacemakers that are properly implanted and programmed can correct a patient's arrhythmia and resolve related symptoms.

### Morbidity and mortality rates

In the United States, patients experience complications in 3.3% and 3.8% of cases, with those over 65 years of age demonstrating a slightly higher complication rate of 6.1%. The most common complications include lead dislodgement, pneumothorax (collapsed lung), and cardiac perforation. The risk of **death** is less than 0.5% throughout the course of the hospital stay.

## Pain management

### Definition

Pain itself is defined by the International Association for the Study of Pain (IASP) as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage." Thus, pain management encompasses all interventions used to understand and ease pain, and if possible to alleviate the cause of the pain.

### Purpose

Pain serves to alert a person to potential or actual damage to the body. The definition of damage is quite broad: pain can arise from injury as well as disease. After the message is received and interpreted, further pain can be counterproductive. Pain can have a negative impact on a person's quality of life and impede recovery from illness or injury, thus contributing to escalating health care costs. Unrelieved pain can become a syndrome in its own right and cause a downward spiral in a person's health and emotional outlook. Managing pain properly facilitates recovery, prevents additional health complications, and improves an individual's quality of life.

Yet the experiencing of pain is a completely unique occurrence for each person, a complex combination of several factors other than the pain itself. It is influenced by:

- Ethnic and cultural values. In some cultures, tolerating pain is related to showing strength and endurance. In others, pain is considered punishment for misdeeds.
- Age. Many people have been taught that grownups never cry. On the other hand, in some cultures, the

elderly are allowed to complain freely about pain and discomfort.

- Anxiety and stress. This factor is related to being in a strange or unfamiliar place such as a hospital, and the fear of the unknown consequences of the pain and the condition causing it, which can all combined to make pain feel more severe. For patients being treated for pain, knowing the duration of activity of an analgesic leads to anxiety about the return of pain when the drug wears off. This anxiety can make the pain more severe. In addition, patients who interpret their pain as meaning that their disease is recurring or getting worse often experience pain as more severe.
- Fatigue and depression. It is known that pain in itself can actually cause emotional depression. Fatigue from lack of sleep or the illness itself also contributes to depressed feelings.

### Precautions

The perception of pain is an individual experience. Healthcare providers play an important role in understanding their patients' pain. All too often, both physicians and nurses have been found to incorrectly assess the severity of pain. A study reported in the *Journal of Advanced Nursing* evaluated nurses' perceptions of a select group of white American and Mexican-American women patients' pain following gallbladder surgery. Objective assessments of each patient's pain showed little difference between the perceived severities for each group. Yet, the nurses involved in the study consistently rated all patients' pain as less than the patients reported, and with equal consistency, believed that better-educated women born in the United States were suffering more than less-educated Mexican-American women. Nurses from a northern European background were more apt to minimize the severity of pain than nurses from eastern and southern Europe or Africa. The study indicated how healthcare staff, and especially nursing staff, need to be aware of how their own background and experience contributes to how they perceive a person's pain.

Some patient populations are particularly susceptible to inadequate pain management. These include cancer patients; children; trauma victims receiving treatment in hospital emergency departments; and the elderly in **nursing homes**.

### Description

Before considering pain management, a review of pain definitions and mechanisms may be useful. Pain is the means by which the peripheral nervous system

## KEY TERMS

**Acute**—Referring to pain in response to injury or other stimulus that resolves when the injury heals or the stimulus is removed.

**Central nervous system (CNS)**—The part of the nervous system that includes the brain and the spinal cord.

**Chronic**—Referring to pain that endures beyond the term of an injury or painful stimulus. Can also refer to cancer pain, pain from a chronic or degenerative disease, and pain from an unidentified cause.

**Iatrogenic**—Resulting from the activity of the physician.

**Neuropathy**—Nerve damage.

**Neurotransmitter**—Chemicals within the nervous system that transmit information from or between nerve cells.

**Nociceptor**—A nerve cell that is capable of sensing pain and transmitting a pain signal.

**Nonpharmacological**—Referring to therapy that does not involve drugs.

**Parasympathetic nervous system**—That part of the autonomic nervous system consisting of nerves that arise from the cranial and sacral regions and function in opposition to the sympathetic nervous system.

**Peripheral nervous system (PNS)**—Nerves that are outside of the brain and spinal cord.

**Pharmacological**—Referring to therapy that relies on drugs.

**Stimulus**—A factor capable of eliciting a response in a nerve.

**Sympathetic nervous system**—That portion of the autonomic nervous system consisting of nerves that originate in the thoracic and lumbar spinal cord and function in opposition to the parasympathetic nervous system.

(PNS) warns the central nervous system (CNS) of injury or potential injury to the body. The CNS comprises the brain and spinal cord, and the PNS is composed of the nerves that stem from and lead into the CNS. PNS includes all nerves throughout the body, except the brain and spinal cord. Pain is sometimes categorized by its site of origin, either cutaneous (originating in the skin, or subcutaneous tissue, such as a shaving nick or paper cut), deep somatic pain (arising

from bone, ligaments and tendons, nerves, or veins and arteries), or visceral (appearing as a result of stimulation of pain receptor nerves around such organs as the brain, lungs, or stomach and intestines).

A pain message is transmitted to the CNS by special PNS nerve cells called nociceptors, which are distributed throughout the body and respond to different stimuli depending on their location. For example, nociceptors that extend from the skin are stimulated by such sensations as pressure, temperature, and chemical changes.

When a nociceptor is stimulated, neurotransmitters are released within the cell. Neurotransmitters are chemicals found within the nervous system that facilitate nerve cell communication. The nociceptor transmits its signal to nerve cells within the spinal cord, which conveys the pain message to the thalamus, a specific region in the brain.

Once the brain has received and processed the pain message and coordinated an appropriate response, pain has served its purpose. The body uses natural pain-killers called endorphins to derail further pain messages from the same source. However, these natural pain-killers may not adequately dampen a continuing pain message. Also, depending on how the brain has processed the pain information, certain hormones such as prostaglandins may be released. These hormones enhance the pain message and play a role in immune system responses to injury, such as inflammation. Certain neurotransmitters, especially substance P and calcitonin gene-related peptide, actively enhance the pain message at the injury site and within the spinal cord.

Pain is generally divided into two additional categories: acute and chronic. Nociceptive pain, or the pain that is transmitted by nociceptors, is typically called acute pain. This kind of pain is associated with injury, headaches, disease, and many other conditions. Response to acute pain is made by the sympathetic nervous system (the nerves responsible for the fight-or-flight response of the body). It normally resolves once the condition that precipitated it is resolved.

There are some disorders that produce pain that does not resolve following the disorder. Even after healing or a cure has been achieved, the brain continues to perceive pain. In this situation, the pain may be considered chronic. Chronic pain is within the province of the parasympathetic nervous system, and the changeover occurs as the body attempts to adapt to the pain. The time limit used to define chronic pain typically ranges from three to six months, although some healthcare professionals prefer a more flexible definition and consider chronic pain as pain that

endures beyond a normal healing time. The pain associated with cancer, persistent and degenerative conditions, and neuropathy, or nerve damage, is included in the chronic category. Also, unremitting pain that lacks an identifiable physical cause such as the majority of cases of low back pain may be considered chronic. The underlying biochemistry of chronic pain appears to be different from that of acute nociceptive pain.

It has been hypothesized that uninterrupted and unrelenting pain can induce changes in the spinal cord. In the past, severing a nerve's connection to the CNS has treated intractable pain. However, the lack of any sensory information being relayed by that nerve can cause pain transmission in the spinal cord to go into overdrive, as evidenced by the phantom limb pain experienced by amputees. Evidence is accumulating that unrelenting pain or the complete lack of nerve signals increases the number of pain receptors in the spinal cord. Nerve cells in the spinal cord may also begin secreting pain-amplifying neurotransmitters independent of actual pain signals from the body. Immune chemicals, primarily cytokines, may play a prominent role in such changes.

### *Managing pain*

Considering the different causes and types of pain, as well as its nature and intensity, management usually requires a multidisciplinary approach. The elements of this approach include treating the underlying cause of pain, pharmacological and non-pharmacological therapies, and some invasive (surgical) procedures.

Treating the cause of pain underlies the basic strategy of pain management. Injuries are repaired, diseases are diagnosed, and certain encounters with pain can be anticipated and treated prophylactically (by prevention). However, there are no guarantees of immediate relief from pain. Recovery can be impeded by pain and quality of life can be damaged. Therefore, pharmacological and other therapies have developed over time to address these aspects of disease and injury.

**PHARMACOLOGICAL OPTIONS.** General guidelines developed by the World Health Organization (WHO) have been developed for pain management. These guidelines operate upon the three-step ladder approach, including:

- Mild pain is alleviated with acetaminophen or a non-steroidal anti-inflammatory drug (NSAID). NSAIDs and acetaminophen are available as over-the-counter (OTC) and prescription medications, and are frequently the initial pharmacological treatment for pain. These drugs can also be used as adjuncts to the

other drug therapies that might require a doctor's prescription. NSAIDs include aspirin, ibuprofen (Motrin, Advil, Nuprin), naproxen sodium (Aleve), and ketoprofen (Orudis KT). These drugs are used to treat pain from inflammation and work by blocking production of pain-enhancing neurotransmitters. Acetaminophen is also effective against pain, but its ability to reduce inflammation is limited. NSAIDs and acetaminophen are effective for most forms of acute (sharp, but of a short duration) pain.

- Mild to moderate pain is eased with a milder opioid medication, plus acetaminophen or NSAIDs. Opioids include both drugs derived from the opium poppy, such as morphine and codeine, and synthetic drugs based on the structure of opium. This drug class includes drugs such as oxycodone, methadone, and meperidine (Demerol). They provide pain relief by binding to specific opioid receptors in the brain and spinal cord. One drawback of opioids, however, is that they frequently cause constipation because they slow down the rhythmic muscular contractions of the intestines that push food along during the process of digestion.
- Moderate to severe pain is treated with stronger opioid drugs, plus acetaminophen or NSAIDs. Morphine is sometimes referred to as the gold standard of palliative care as it is not expensive; can be given by starting with smaller doses and gradually increased; and is highly effective over a long period of time. It can also be given by a number of different routes, including by mouth, rectally, or by injection.

Although antidepressant drugs were developed to treat depression, it has been discovered that they are also effective in combating chronic headaches, cancer pain, and pain associated with nerve damage. Antidepressants that have been shown to have analgesic (pain-reducing) properties include amitriptyline (Elavil), trazodone (Desyrel), and imipramine (Tofranil). Anticonvulsant drugs share a similar background with antidepressants. Developed to treat epilepsy, anticonvulsants were found to relieve pain as well. Drugs such as phenytoin (Dilantin) and carbamazepine (Tegretol) are prescribed to treat the pain associated with nerve damage.

In some cases, chronic pain caused by complications of diabetes or cancer can be eased by administering local anesthetics. The most commonly used are mexiletine (Mexitol) and a lidocaine patch.

**Corticosteroids** are another class of drugs commonly given to manage chronic pain caused by arthritis or other diseases affecting the muscles and joints; they may also be given to control nausea. Dexamethasone

(Decadron) and prednisone are the most commonly used corticosteroids in pain management. They work by reducing inflammation and suppressing the immune system.

Close monitoring of the effects of pain medications is required in order to assure that adequate amounts of medication are given to produce the desired pain relief. When a person is comfortable with a certain dosage of medication, oncologists typically convert to a long-acting version of that medication. Transdermal fentanyl patches (Duragesic) are a common example of a long-acting opioid drug often used for cancer pain management. A patch containing the drug is applied to the skin and continues to deliver the drug to the person for an average of three days. Pumps are also available that provide an opioid medication upon demand when the person is experiencing pain. By pressing a button, they can release a set dose of medication into an intravenous solution or an implanted catheter. Another mode of administration involves implanted catheters that deliver pain medication directly to the spinal cord. Because these pumps offer the patient some degree of control over the amount of analgesic administered, the system, commonly called **patient-controlled analgesia (PCA)**, reduces the level of anxiety about availability of pain medication. Delivering drugs in this way can reduce side effects and increase the effectiveness of the drug. Research is underway to develop toxic substances that act selectively on nerve cells that carry pain messages to the brain. These substances would kill the selected cells and stop transmission of the pain message.

**NONPHARMACOLOGICAL OPTIONS.** Pain treatment options that do not use drugs are often used as adjuncts to, rather than replacements for, drug therapy. One of the benefits of nondrug therapies is that an individual can take a more active role in pain management. Such relaxation techniques as yoga and meditation are used to focus the brain elsewhere than on the pain, decrease muscle tension, and reduce stress. Tension and stress can also be reduced through **biofeedback**, in which an individual consciously attempts to modify skin temperature, muscle tension, blood pressure, and heart rate.

Hypnosis is another nonpharmacological option for pain relief. Although doctors do not yet fully understand how hypnosis works, it is used successfully in some patients to manage pain related to childbirth, oral surgery, burn treatment, and other procedures that require the patient to remain conscious.

Participating in normal activities and exercising can also help control pain levels. Through physical

therapy, an individual learns beneficial exercises for reducing stress, strengthening muscles, and staying fit. Regular **exercise** has been linked to production of endorphins, the body's natural painkillers.

Acupuncture involves the insertion of small needles into the skin at key points. Acupressure uses these same key points, but involves applying pressure rather than inserting needles. Both of these methods may work by prompting the body to release endorphins. Applying heat or being massaged are very relaxing and help reduce stress. Transcutaneous electrical nerve stimulation (TENS) applies a small electric current to certain parts of nerves, potentially interrupting pain signals and inducing release of endorphins. To be effective, use of TENS should be medically supervised.

**INVASIVE PROCEDURES.** There are three types of invasive procedures that may be used to manage or treat pain: anatomic, augmentative, and ablative. These procedures involve surgery, and certain guidelines should be followed before carrying out a procedure with permanent effects. First, the cause of the pain must be clearly identified. Next, surgery should be done only if noninvasive procedures are ineffective. Third, any psychological issues should be addressed. Finally, there should be a reasonable expectation of success.

Anatomic procedures involve correcting the injury or removing the cause of pain. Relatively common anatomic procedures are decompression surgeries such as repairing a herniated disk in the lower back or relieving the nerve compression related to carpal tunnel syndrome. Another anatomic procedure is neurolysis, also called a nerve block, which involves destroying a portion of a peripheral nerve.

Augmentative procedures include electrical stimulation or direct application of drugs to the nerves that are transmitting the pain signals. Electrical stimulation works on the same principle as TENS. In this procedure, instead of applying the current across the skin, electrodes are implanted to stimulate peripheral nerves or nerves in the spinal cord. Augmentative procedures also include implanted drug-delivery systems. In these systems, catheters are implanted in the spine to allow direct delivery of drugs to the CNS.

Ablative procedures are characterized by severing a nerve and disconnecting it from the CNS. However, this method may not address potential alterations within the spinal cord. These changes perpetuate pain messages and do not cease, even when the connection between the sensory nerve and the CNS is severed. With growing understanding of neuropathic pain and development of less invasive procedures, ablative procedures are used less frequently. However,

they do have applications in select cases of peripheral neuropathy, cancer pain, and other disorders.

## Preparation

Prior to beginning management, the patient's pain should be thoroughly evaluated, including a psychosocial as well as a physical assessment. Pain scales or questionnaires can be administered by a member of the healthcare team, although there is no single questionnaire that is universally accepted as of 2007. Some questionnaires are verbal, while others use pictures or drawings to help the patient describe the pain. Some questionnaires are filled out by the patient, while others may be given to relatives or friends to complete. It is often necessary to ask other family members to complete a pain questionnaire if the patient is cognitively impaired.

In spite of their limitations, questionnaires and self-report forms do allow healthcare workers to better understand the pain being suffered by the patient. Evaluation also includes physical examinations and diagnostic tests to determine the underlying physical causes of the pain. Some evaluations require assessments from several viewpoints, including neurology, psychiatry and psychology, and physical therapy. If the pain is caused by a medical procedure, management consists of anticipating the type and intensity of associated pain and managing it preemptively.

Nurses or physicians often take what is called a pain history. This history will help to provide important information that can help health care providers to better manage the patient's pain. A typical pain history includes the following questions:

- Where is the pain located?
- On a scale of 1 to 10, with 1 indicating the least pain, how would the person rate the pain being experienced?
- What does the pain feel like?
- When did (or does) the pain start?
- How long has the person had it?
- Is the person sometimes free of pain?
- Is the pain constant, or is it episodic?
- Does the person know of anything that triggers the pain or makes it worse?
- Does the person have other symptoms (nausea, dizziness, blurred vision, etc.) during or after the pain?
- What pain medications or other measures has the person found to help in easing the pain?
- How does the pain affect the person's ability to carry on normal activities?
- What does it mean to the person that he or she is experiencing pain?

## Aftercare

An assessment by nursing staff as well as other healthcare providers should be made to determine the effectiveness of the pain management interventions employed. There are objective, measurable signs and symptoms of pain that can be looked for. The goal of good pain management is the absence of these signs. Signs of acute pain include:

- rise in pulse and blood pressure
- more rapid breathing
- perspiring profusely, clammy skin
- taut muscles
- more tense appearance, fast speech, very alert
- unusually pale skin
- dilated pupils of the eye

Signs of chronic pain include:

- lower pulse and blood pressure
- changeable breathing pattern
- warm, dry skin
- nausea and vomiting
- slow or monotone speech
- inability or difficulty in getting out of bed and performing activities of daily living (ADLs)
- constricted pupils of the eye

When these signs are absent and the patient appears to be comfortable, healthcare providers can consider their interventions to have been successful. It is also important to document interventions used, and which ones were successful.

## Risks

Owing to toxicity over the long term, some drugs can only be used for acute pain or as adjuncts in chronic pain management. NSAIDs have the well-known side effect of causing gastrointestinal bleeding, and long-term use of **acetaminophen** has been linked to kidney and liver damage. Other drugs, especially narcotics, have such serious side effects as constipation, drowsiness, and nausea. Serious side effects can also accompany pharmacological therapies; mood swings, confusion, bone thinning, cataract formation, increased blood pressure, and other problems may discourage or prevent use of some **analgesics**.

Nonpharmacological therapies carry little or no risks. However, individuals recovering from serious illness or injury should consult with the health care providers or physical therapists before making use of adjunct therapies. Invasive procedures carry risks similar to other surgical procedures, such as infection,

reaction to anesthesia, and iatrogenic (injury as a result of treatment) injury.

A traditional concern about narcotics use has been the risk of promoting addiction. As narcotic use continues over time, the body becomes accustomed to the drug and adjusts normal functions to accommodate to its presence. Therefore, to elicit the same level of action, it is necessary to increase dosage over time. As dosage increases, an individual may become physically dependent on narcotic drugs.

However, physical dependence is different from psychological addiction. Physical dependence is characterized by discomfort if drug administration suddenly stops, while psychological addiction is characterized by an overpowering craving for the drug for reasons other than pain relief. Psychological addiction is a very real and necessary concern in some instances, but it should not interfere with a genuine need for narcotic pain relief. However, caution must be taken with people who have a history of addictive behavior.

## Normal results

Effective application of pain management techniques reduces or eliminates acute or chronic pain. This treatment can improve an individual's quality of life and aid in recovery from injury and disease.

## Pallidotomy

### Definition

Pallidotomy is the destruction of a small region of the brain, the globus pallidus internus, in order to treat some of the symptoms of Parkinson's disease.

### Purpose

The symptoms of Parkinson's disease (PD) include rigidity, slowed movements, and tremor, along with postural instability and a variety of non-motor symptoms (i.e., symptoms not involving movement). These symptoms are due to degeneration of a small portion of the brain called the substantia nigra, the cells of which secrete the chemical dopamine that influences cells in another brain region called the globus pallidus internus

**A CT scan of a surgical probe entering a patient's brain.** (John Greim / Photo Researchers, Inc.)

(GPi). Together with other brain regions, these two structures take part in complex control loops that govern certain aspects of movement and, when substantia nigra cells degenerate, these loops are disrupted and movements become unregulated, producing the symptoms of Parkinson's disease.

The effects of dopamine on the brain can be mimicked by the drug levodopa; levodopa therapy is the mainstay of PD treatment in its early stages. Unfortunately, levodopa becomes less effective over time, and also produces unwanted and uncontrolled movements called dyskinesias. This may occur after five to 10 years or more of successful levodopa treatment. Once a patient can no longer be treated effectively with levodopa, surgery is considered as a management option. Pallidotomy is one of the main surgical options for treatment of advanced PD.

The effect of dopamine on the cells of the GPi is to suppress them by preventing them from firing. Pallidotomy mimics this action by permanently destroying the GPi cells. It may seem odd that the treatment for degeneration of one brain area is to destroy another, but in the absence of dopamine, the GPi cells are overactive, and therefore, eliminating them is an appropriate treatment.

The GPi has two halves that control movements on opposite sides: right controls left, left controls right. Unilateral (one-sided) pallidotomy may be used

if symptoms are markedly worse on one side or the other, or if the risks from bilateral (two-sided) pallidotomy are judged to be too great.

## Demographics

Parkinson's disease affects approximately one million Americans. The peak incidence is approximately at age 62, but young-onset PD can occur as early as age 40. Because young-onset patients live with their disease for so many more years, they are more likely to become candidates for surgery than older-onset patients. In addition, younger patients tend to do better with surgery and suffer fewer adverse effects from the surgery. Approximately 5% of older PD patients receive one form or another of PD surgery; many more develop the symptoms for which surgery may be effective, but either develop them at an advanced age, making surgery inadvisable, or decide the risks of surgery are not worth the potential benefit, or do not choose surgery for some other reason.

## Description

Pallidotomy requires the insertion of a long needle-like probe deep into the brain through a hole in the top of the skull. In order to precisely locate the GPi target, and to ensure the probe is precisely placed in the target, a "stereotactic frame" is used. This device is a rigid frame attached to the patient's head, providing an immobile three-dimensional coordinate system, which can be used to precisely track the location of the GPi and the movement of the probe.

For unilateral pallidotomy, a single "burr hole" is made in the top of the skull; bilateral pallidotomy requires two holes. A strong topical anesthetic is used to numb the shaved area before this hole is drilled. Since there are no pain receptors in the brain, there is no need for deeper anesthetic. In addition, the patient must remain awake in order to report any sensory changes during the surgery. The lesion made in the GPi is very close to the optic tract that carries visual information from the eyes to the rear of the brain. Visual changes may indicate the probe is too close to this region.

Once the burr hole is made, the surgeon inserts a microelectrode probe, which is used to more precisely locate the GPi. Electrical stimulation of the brain through the electrode can help determine exactly which structure is being stimulated. This is harmless, but may cause twitching, light flashes, or other sensations. A contrast dye may also be injected into the spinal fluid, which allows the surgeon to visualize the brain's structure using one or more imaging techniques. During the procedure, the patient will be asked to make

various movements to assist in determining the location of the electrode.

When the proper target is located, the electrode tip is briefly heated, carefully destroying the surrounding tissue to about the size of a pearl. If bilateral pallidotomy is being performed, the localizing and lesioning will be repeated on the other side.

## Diagnosis/Preparation

Pallidotomy is performed in patients with Parkinson's disease who are still responsive to levodopa, but who have developed disabling drug treatment complications known as motor fluctuations, including rapid wearing off of drug effect, unpredictable "off states" (times of low levodopa levels in the blood), and disabling dyskinesias. Those who are very elderly, demented, or with other significant medical conditions that would be compromised by surgery are usually not candidates for pallidotomy.

The surgical candidate should discuss all the surgical options with the neurologist before deciding on pallidotomy. A full understanding of the risks and potential benefits must be understood before consenting to the surgery.

The patient will undergo a variety of medical tests, and one or more types of neuroimaging procedures, including **magnetic resonance imaging (MRI)**, computed tomography (CT) scanning, **angiography** (imaging the brain's blood vessels), and **ventriculography** (imaging the brain's ventricles). On the day of the surgery, the stereotactic frame will be fixed to the patient's head. First, a local anesthetic is applied at the four sites where the frame's pins contact the head; there may nonetheless be some initial discomfort. A final MRI is done with the frame in place to help set the coordinates of the GPi in relation to the frame.

The patient will receive a mild sedative to ease the anxiety of the procedure.

## Aftercare

The procedure requires several hours. Some centers perform pallidotomy as an outpatient procedure, sending the patient home the same day. Most centers keep the patient overnight or longer for observation. Patients will feel improved movement immediately. Medications may be adjusted somewhat to accommodate the changes in symptoms.

## Risks

The key to successful outcome in pallidotomy is extremely precise placement of the electrode. While

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

Pallidotomy is performed in the hospital by a neurosurgeon, in coordination with the patient's neurologist.

there are several controversies in the field of PD surgery, all experts agree that risks are reduced in procedures performed by the most experienced neurosurgeons.

Hemorrhage in the brain is a possible complication, as is infection. There are small but significant risks of damage to the optic tract, which can cause visual deficits. Speech impairments may also occur, including difficulty retrieving words and slurred speech. Some cognitively fragile patients may become even more impaired after surgery.

### Normal results

Pallidotomy improves the motor ability of patients, especially during "off" periods. Studies show the procedure generally improves tremor, rigidity, and slowed movements by 25–60%. Dyskinesias typically improve by 75% or more. Improvements from unilateral pallidotomy are primarily on the side opposite the surgery. Balance does not improve, nor do non-motor symptoms such as drooling, constipation, and orthostatic hypotension (lightheadness on standing).

### Morbidity and mortality rates

Among the best surgeons, the risk of serious morbidity or mortality is 1–2%. Hemorrhage may occur in 2–6%, visual field deficits in 0–6%, and weakness in 2–8%. Most patients gain weight after surgery.

### Alternatives

Patients whose symptoms are well managed by drugs are not recommended for surgery, and significant effort will usually be made to adjust medications to control symptoms before surgery is considered.

Thalamotomy, surgery to the thalamus, was recommended in the past to control tremor. It is rarely performed today, and few centers would consider thalamotomy for any patient unless tremor was the only troubling and uncontrolled symptom.

Deep-brain stimulation (DBS) of the GPi is an alternative treatment in widespread use, as is DBS of another brain region, the subthalamic nucleus. Both

## QUESTIONS TO ASK THE DOCTOR

- How many pallidotomies has the neurosurgeon performed?
- What is the surgeon's own rate of serious complications?
- Would deep brain stimulation of the subthalamic nucleus be appropriate for me?
- How will my medications change after the operation?

procedures use permanently implanted, programmable electrodes to deliver a very small, continuous electric current to the target region. This has the same effect as a lesion, but is adjustable. DBS of the subthalamic nucleus typically produces better symptomatic results than either DBS to the GPi or pallidotomy. However, both forms of DBS carry the risk of long-term complications from the implanted hardware, as well as other risks.

Pancreas removal see **Pancreatectomy**

## Pancreas transplantation

### Definition

Pancreas transplantation is a surgical procedure in which a diseased pancreas is replaced with a healthy pancreas that has been obtained from an immunologically compatible cadaver or living donor.

### Purpose

The pancreas secretes insulin that regulates glucose (blood sugar) metabolism. Patients with type I

**The pancreas transplantation procedure.** (BSIP/Phototake. Reproduced by permission.)

diabetes have experienced partial or complete damage to the insulin-producing beta cells of the pancreas. Consequently, they are unable to generate sufficient insulin to control blood glucose levels. Long-term uncontrolled high blood glucose levels can cause damage to every system of the body, so type I patients must inject insulin to do the work of the beta cells. Pancreas transplantation allows the body to once again make

and secrete its own insulin, and establishes insulin independence for these individuals.

### Demographics

It is estimated that over one million people in the United States have type 1 diabetes mellitus (also called insulin-dependant diabetes or juvenile diabetes). Among

these individuals, the best candidates for pancreas transplantation are typically:

- between the ages of 20 and 40
- those who have extreme difficulty regulating their glucose levels with insulin therapy (a condition called brittle diabetes)
- those who have few secondary complications of diabetes
- those who are in good cardiovascular health

A pancreas-only transplant is an uncommon procedure, with only 163 procedures occurring in the United States in 2001. More common is the combined kidney-pancreas transplant, which was performed on 885 patients the same year. An additional 305 patients received a PAK, or pancreas after kidney transplant, according to the United Network for Organ Sharing (UNOS).

### Description

Once a donor pancreas is located and tissue typing deems it compatible, the patient is contacted and prepared for surgery. Blood tests, a **chest x ray**, and an **electrocardiogram** (ECG) are performed and an intravenous (IV) line is started for fluid and medication administration. Once the transplant procedure is ready to start, **general anesthesia** is administered.

The surgeon makes an incision under the ribs and locates the pancreas and duodenum. The pancreas and duodenum (part of the small intestine) are removed. The new pancreas and duodenum are then connected to the patient's duodenum, and the blood vessels are sutured together to restore blood flow to the new pancreas. The patient's original pancreas is left in place.

Replacing the duodenum allows the pancreas to drain into the gastrointestinal system. The transplant can also be done creating bladder drainage. Bladder drainage makes it easier to monitor organ rejection because pancreatic secretions can be measured in the patient's urine. Once the new pancreas is in place, the abdomen and skin are sutured closed. This surgery is often done at the same time as kidney **transplant surgery**.

### Diagnosis/Preparation

After the patient and doctor have decided on a pancreas transplant, a complete immunological study is performed to match the patient to a donor. An extensive medical history and **physical examination** is performed, including radiological exams, blood and urine tests, and psychological evaluation. Once the patient is approved for transplant, he or she will be placed on the United Network for Organ Sharing

## KEY TERMS

**Cadaver organ**—A pancreas, kidney, or other organ from a brain-dead organ donor.

**Duodenum**—The section of the small intestine immediately after the stomach.

(UNOS) Organ Center waiting list. The timing of surgery depends on the availability of a donated living or cadaver organ.

### Aftercare

Patients receiving a pancreas transplantation are monitored closely for organ rejection. The average hospital stay is three weeks, and it takes about six months to recover from surgery. Patients will take **immunosuppressant drugs** for the rest of their lives.

### Risks

Diabetes and poor kidney function greatly increase the risk of complications from anesthesia during surgery. Organ rejection, excessive bleeding, and infection are other major risks associated with this surgery.

The reason simultaneous kidney-pancreas transplants and pancreas after kidney transplants are performed more frequently than pancreas only transplants is the relative risk of immunosuppressant drugs in people with diabetes. People with type I diabetes are already at risk for autoimmune problems, are more prone to infections, and have a complicated medical history that makes suppressing the immune system unadvisable.

On the other hand, diabetes is also the number one cause of chronic kidney failure, or end-stage renal disease (ESRD), which makes this group more likely to eventually require a kidney transplant for survival. In those patients with diabetes who will receive or are already receiving immunosuppressive treatment for a life-saving kidney transplant, a pancreas transplant can return their ability to self-produce insulin.

Patients with type I diabetes considering pancreas transplantation alone must weigh the risks and benefits of the procedure and decide with their doctors whether life-long treatment with immunosuppressive drugs is preferable to life-long insulin dependence.

### Normal results

In a successful transplant, the pancreas begins producing insulin, bringing the regulation of glucose

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

A pancreas transplant is performed by a transplant surgeon in one of over 200 UNOS-approved hospitals nationwide. The patient must go through an evaluation procedure at his or her hospital of choice to get on the UNOS national waiting list and the UNOS Organ Center's UNet database.

back under control. Natural availability of insulin prevents the development of additional complications associated with diabetes, including kidney damage, vision loss, and nerve damage. Many patients report an improved quality of life.

### Morbidity and mortality rates

In their 2002 Annual Report, the Organ Procurement and Transplant Network (OPTN) reported that the patient survival rate for pancreas transplant alone was 98.6% after one year and 86% after three years. Survival rates for pancreas-kidney transplant recipients were 95.1% after one year and 89.2% after three years.

### Alternatives

Innovations in islet cell transplants, a procedure that involves transplanting a culture of the insulin-producing islet cells of a healthy pancreas to a patient with type I diabetes, have increased the frequency of this procedure. The Edmonton Protocol, a type of islet cell transplant developed in 1999 by Dr. James Shapiro at the University of Alberta (Canada), uses a unique immunosuppressant drug regimen that has dramatically improved success rates of the islet transplant procedure. As of early 2003, the Edmonton Protocol was still considered investigational in the United States, and a number of clinical trials were ongoing.

## Pancreatectomy

### Definition

A pancreatectomy is the surgical removal of the pancreas. A pancreatectomy may be total, in which case the entire organ is removed, usually along with the spleen, gallbladder, common bile duct, and portions of the small intestine and stomach. A pancreatectomy may also be distal, meaning that only the body and tail of the pancreas are removed, leaving the head of the organ attached. When the duodenum is removed along with all or part of the pancreas, the procedure is called a pancreaticoduodenectomy, which surgeons sometimes refer to as "Whipple's procedure." Pancreaticoduodenectomies are increasingly used to treat a variety of malignant and benign diseases of the pancreas. This procedure often involves removal of the regional lymph nodes as well.

### Purpose

A pancreatectomy is the most effective treatment for cancer of the pancreas, an abdominal organ that

## KEY TERMS

**Chemotherapy**—A cancer treatment that uses synthetic drugs to destroy the tumor either by inhibiting the growth of the cancerous cells or by killing the cancer cells.

**Computed tomography (CT) scan**—An imaging technique that creates a series of pictures of areas inside the body, taken from different angles. The pictures are created by a computer linked to an x-ray machine.

**Endoscopic retrograde cholangiopancreatography (ERCP)**—A procedure to x-ray the ducts (tubes) that carry bile from the liver to the gallbladder and from the gallbladder to the small intestine.

**Laparoscopy**—In this procedure, a laparoscope (a thin, lighted tube) is inserted through an incision in the abdominal wall to determine if the cancer is within the pancreas only or has spread to nearby tissues and if it can be removed by surgery later. Tissue samples may be removed for biopsy.

**Magnetic resonance imaging (MRI)**—A procedure in which a magnet linked to a computer is used to create detailed pictures of areas inside the body.

**Pancreas**—A large gland located on the back wall of the abdomen, extending from the duodenum (first part of the small intestine) to the spleen. The pancreas produces enzymes essential for digestion, and

the hormones insulin and glucagon, which play a role in diabetes.

**Pancreaticoduodenectomy**—Removal of all or part of the pancreas along with the duodenum. Also known as “Whipple’s procedure” or “Whipple’s operation.”

**Pancreatitis**—Inflammation of the pancreas, either acute (sudden and episodic) or chronic, usually caused by excessive alcohol intake or gallbladder disease.

**Positron emission tomography (PET) scan**—An imaging system that creates a picture showing the location of tumor cells in the body. A substance called radionuclide dye is injected into a vein, and the PET scanner rotates around the body to create the picture. Malignant tumor cells show up brighter in the picture because they are more active and take up more dye than normal cells.

**Radiation therapy**—A treatment using high energy radiation from x-ray machines, cobalt, radium, or other sources.

**Ultrasonogram**—A procedure where high-frequency sound waves that cannot be heard by human ears are bounced off internal organs and tissues. These sound waves produce a pattern of echoes which are then used by the computer to create sonograms, or pictures of areas inside the body.

secretes digestive enzymes, insulin, and other hormones. The thickest part of the pancreas near the duodenum (a part of the small intestine) is called the head, the middle part is called the body, and the thinnest part adjacent to the spleen is called the tail.

While surgical removal of tumors in the pancreas is the preferred treatment, it is only possible in the 10–15% of patients who are diagnosed early enough for a potential cure. Patients who are considered suitable for surgery usually have small tumors in the head of the pancreas (close to the duodenum, or first part of the small intestine), have jaundice as their initial symptom, and have no evidence of metastatic disease (spread of cancer to other sites). The stage of the cancer will determine whether the pancreatectomy to be performed should be total or distal.

A partial pancreatectomy may be indicated when the pancreas has been severely injured by trauma, especially injury to the body and tail of the pancreas. While such surgery removes normal pancreatic tissue as well, the long-term consequences of this surgery are

minimal, with virtually no effects on the production of insulin, digestive enzymes, and other hormones.

Chronic pancreatitis is another condition for which a pancreatectomy is occasionally performed. Chronic pancreatitis—or continuing inflammation of the pancreas that results in permanent damage to this organ—can develop from long-standing, recurring episodes of acute (periodic) pancreatitis. This painful condition usually results from alcohol abuse or the presence of gallstones. In most patients with the alcohol-induced disease, the pancreas is widely involved, therefore, surgical correction is almost impossible.

### Description

A pancreatectomy can be performed through an open surgery technique, in which case one large incision is made, or it can be performed laparoscopically, in which case the surgeon makes four small incisions to insert tube-like **surgical instruments**. The abdomen is filled with gas, usually carbon dioxide, to help the surgeon view the abdominal cavity. A camera is

inserted through one of the tubes and displays images on a monitor in the **operating room**. Other instruments are placed through the additional tubes. The laparoscopic approach allows the surgeon to work inside the patient's abdomen without making a large incision.

If the pancreatectomy is partial, the surgeon clamps and cuts the blood vessels, and the pancreas is stapled and divided for removal. If the disease affects the splenic artery or vein, the spleen is also removed.

If the pancreatectomy is total, the surgeon removes the entire pancreas and attached organs. He or she starts by dividing and detaching the end of the stomach. This part of the stomach leads to the small intestine, where the pancreas and bile duct both attach. In the next step, he removes the pancreas along with the connected section of the small intestine. The common bile duct and the gallbladder are also removed. To reconnect the intestinal tract, the stomach and the bile duct are then connected to the small intestine.

During a pancreatectomy procedure, several tubes are also inserted for **postoperative care**. To prevent tissue fluid from accumulating in the operated site, a temporary drain leading out of the body is inserted, as well as a **gastrostomy** or g-tube leading out of the stomach in order to help prevent nausea and vomiting. A jejunostomy or j-tube may also be inserted into the small intestine as a pathway for supplementary feeding.

### Diagnosis/Preparation

Patients with symptoms of a pancreatic disorder undergo a number of tests before surgery is even considered. These can include ultrasonography, x-ray examinations, computed tomography scans (CT scan), and **endoscopic retrograde cholangiopancreatography** (ERCP), a specialized imaging technique to visualize the ducts that carry bile from the liver to the gallbladder. Tests may also include **angiography**, another imaging technique used to visualize the arteries feeding the pancreas, and needle aspiration cytology, in which cells are drawn from areas suspected to contain cancer. Such tests are required to establish a correct diagnosis for the pancreatic disorder and in the planning the surgery.

Since many patients with pancreatic cancer are undernourished, appropriate nutritional support, sometimes by tube feedings, may be required prior to surgery.

Some patients with pancreatic cancer deemed suitable for a pancreatectomy will also undergo chemotherapy and/or radiation therapy. This treatment is aimed at shrinking the tumor, which will improve the chances for successful surgical removal. Sometimes,

patients who are not initially considered surgical candidates may respond so well to chemoradiation that surgical treatment becomes possible. Radiation therapy may also be applied during the surgery (intraoperatively) to improve the patient's chances of survival, but this treatment is not yet in routine use. Some studies have shown that intraoperative radiation therapy extends survival by several months.

Patients undergoing distal pancreatectomy that involves removal of the spleen may receive preoperative medication to decrease the risk of infection.

### Aftercare

Pancreatectomy is major surgery. Therefore, extended hospitalization is usually required with an average hospital stay of two to three weeks.

Some pancreatic cancer patients may also receive combined chemotherapy and radiation therapy after surgery. This additional treatment has been clearly shown to enhance survival rates.

After surgery, patients experience pain in the abdomen and are prescribed pain medication. Follow-up exams are required to monitor the patient's recovery and remove implanted tubes.

A total pancreatectomy leads to a condition called pancreatic insufficiency, because food can no longer be normally processed with the enzymes normally produced by the pancreas. Insulin secretion is likewise no longer possible. These conditions are treated with pancreatic enzyme replacement therapy, which supplies digestive enzymes; and with insulin injections. In some case, distal pancreatectomies may also lead to pancreatic insufficiency, depending on the patient's general health condition before surgery and on the extent of pancreatic tissue removal.

### Risks

There is a fairly high risk of complications associated with any pancreatectomy procedure. A recent Johns Hopkins study documented complications in 41% of cases. The most devastating complication is postoperative bleeding, which increases the mortality risk to 20–50%. In cases of postoperative bleeding, the patient may be returned to surgery to find the source of hemorrhage, or may undergo other procedures to stop the bleeding.

One of the most common complications from a pancreaticoduodenectomy is delayed gastric emptying, a condition in which food and liquids are slow to leave the stomach. This complication occurred in 19% of patients in the Johns Hopkins study. To manage

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

A pancreatectomy is performed by a surgeon trained in gastroenterology, the branch of medicine that deals with the diseases of the digestive tract. An anesthesiologist is responsible for administering anesthesia and the operation is performed in a hospital setting, with an oncologist on the treatment team if pancreatic cancer motivated the procedure.

this problem, many surgeons insert feeding tubes at the original operation site, through which nutrients can be fed directly into the patient's intestines. This procedure, called enteral nutrition, maintains the patient's nutrition if the stomach is slow to recover normal function. Certain medications, called promotility agents, can help move the nutritional contents through the gastrointestinal tract.

The other most common complication is pancreatic anastomotic leak. This is a leak in the connection that the surgeon makes between the remainder of the pancreas and the other structures in the abdomen. Most surgeons handle the potential for this problem by checking the connection during surgery.

### Normal results

After a total pancreatectomy, the body loses the ability to secrete insulin, enzymes, and other substances; therefore, the patient has to take supplements for the rest of his or her life.

Patients usually resume normal activities within a month after surgery, although they are asked to avoid heavy lifting for six to eight weeks and not to drive as long as they take narcotic medication.

When a pancreatectomy is performed for chronic pancreatitis, the majority of patients obtain some relief from pain. Some studies report that one-half to three-quarters of patients become free of pain.

### Morbidity and mortality rates

The mortality rate for pancreatectomy has decreased in recent years to 5–10%, depending on the extent of the surgery and the experience of the surgeon. A study of 650 patients at Johns Hopkins Medical Institution, Baltimore, found that only nine patients, or 1.4%, died from complications related to surgery.

## QUESTIONS TO ASK THE DOCTOR

- What do I need to do before surgery?
- What type of anesthesia will be used?
- How long will it take to recover from the surgery?
- When can I expect to return to work and/or resume normal activities?
- What are the risks associated with a pancreatectomy?
- How many pancreatectomies do you perform in a year?
- Will there be a scar?

Unfortunately, pancreatic cancer is the most lethal form of gastrointestinal malignancy. However, for a highly selective group of patients, a pancreatectomy offers a chance for cure, especially when performed by experienced surgeons. The overall five-year survival rate for patients who undergo pancreatectomy for pancreatic cancer is about 10%; patients who undergo pancreaticoduodenectomy have a 4–5% survival at five years. The risk for tumor recurrence is thought to be unaffected by whether the patient undergoes a total pancreatectomy or a pancreaticoduodenectomy, but is increased when the tumor is larger than 1.2 in (3 cm) and the cancer has spread to the lymph nodes or surrounding tissue.

### Alternatives

Depending on the medical condition, a **pancreas transplantation** may be considered as an alternative for some patients.

## Paracentesis

### Definition

Paracentesis is a minimally invasive procedure that uses a needle to remove fluid from the abdomen.

### Purpose

There are two reasons to take fluid out of the abdomen. One is to analyze it for diagnostic purposes; the other is to relieve pressure. Liquid that accumulates in the abdomen is called ascites. Ascites seeps out of organs for several reasons related either to disease in the organ or fluid pressures that are changing.

#### Liver disease

All the blood flowing through the intestines passes through the liver on its way back to the heart. When progressive disease such as alcohol damage or hepatitis destroys enough liver tissue, the scarring that results shrinks the liver and constricts blood flow. Such scarring of the liver is called cirrhosis. Pressure builds in the intestinal blood circulation, slowing flow and pushing fluid into surrounding tissues. Slowly the

## KEY TERMS

**Ascites**—Fluid in the abdomen.

**Ectopic pregnancy**—A pregnancy occurring outside the womb that often ruptures and requires surgical removal.

**Hepatitis**—An inflammation of the liver.

fluid accumulates in areas with the lowest pressure and greatest capacity. The free space around abdominal organs receives the greatest amount. This space is called the peritoneal space because it is enclosed by a thin membrane called the peritoneum. The peritoneum wraps around nearly every organ in the abdomen, providing many folds and spaces for the fluid to gather.

### Infections

Peritonitis is an infection of the peritoneum that can develop in several ways. Many abdominal organs contain germs that do not occur elsewhere in the body. If they spill their contents into the peritoneum, infection is the result. Infection changes the dynamics of body fluids, causing them to seep into tissues and spaces. The gall bladder, the stomach, any part of the intestine, and most especially the appendix—all cause peritonitis when they leak or rupture. Tuberculosis can infect many organs in the body; it is not confined to the lungs. Tuberculous peritonitis causes ascites.

### Other inflammations

Peritoneal fluid is not just produced by infections. An inflamed pancreas, called pancreatitis, can cause a massive sterile peritonitis when it leaks its digestive enzymes into the abdomen.

### Cancer

Any cancer that begins in or spreads to the abdomen can leak fluid. One particular tumor of the ovary that leaks fluid and results in fluid accumulation is called Meigs' syndrome.

### Kidney disease

Since the kidneys are intimately involved with the body's fluid balance, diseases of the kidney often cause excessive fluid to accumulate. Nephrosis and nephrotic syndrome are the general terms for diseases that

cause the kidneys to retain water and promote its movement into body tissues and spaces.

### Heart failure

The ultimate source of fluid pressure in the body is the heart, whose pumping generates blood pressure. All other pressures in the body are related to blood pressure. As the heart starts to fail, blood backs up, waiting to be pumped. This increases pressure in the veins leading to the heart, particularly below the it where gravity is also pulling blood down. The extra fluid from heart failure is first noticed in the feet and ankles, where gravitational effects are most evident. In the abdomen, the liver swells first, then it and other abdominal organs start to leak.

### Pleural fluid

The other major body cavity (besides the abdomen) is the chest. The tissue in the chest corresponding to the peritoneum is called the pleura, and the space contained within the pleura, between the ribs and the lungs, is called the pleural space. Fluid is often found in both cavities, and fluid from one cavity can find its way into the other.

Fluid that accumulates in the abdomen creates abnormal pressures on organs in the abdomen. Digestion is hindered; blood flow is slowed. Pressure upward on the chest from fluid-filled organs compromises breathing. The kidneys function poorly in the presence of such external pressures and may even fail.

### Description

During paracentesis, special needles puncture the abdominal wall, being careful not to hit internal organs. If fluid is needed only for analysis, less than 7 oz (200 ml) are removed. If pressure relief is an additional goal, many quarts may be removed. Rapid removal of large amounts of fluid can cause blood pressure to drop suddenly. For this reason, the physician will often leave a tube in place so that fluid can be removed slowly, giving the system time to adapt.

A related procedure called culdocentesis removes ascitic fluid from the very bottom of the abdominal cavity through the back of the vagina. This is used most often to diagnose female genital disorders like ectopic pregnancy, which may bleed or exude fluid into the peritoneal space.

Fluid is sent to the laboratory for testing, where cancer and blood cells can be detected, infections identified, and chemical analysis can direct further investigations.

### Aftercare

An adhesive bandage and perhaps a single stitch close the insertion site. Nothing more is required.

### Risks

Risks are negligible. It is remotely possible that an organ could be punctured and bleed or that an infection could be introduced.

### Normal results

A diagnosis of the cause and/or relief from accumulated fluid pressure are the expected results. Fluid will continue to accumulate until the cause is corrected. Repeated procedures may be needed.

Paralytic ileus see **Intestinal obstruction repair**

Parathyroid gland removal see **Parathyroidectomy**

## Parathyroidectomy

### Definition

Parathyroidectomy is the removal of one or more parathyroid glands. A person usually has four parathyroid glands, although the exact number may vary from three to seven. The glands are located in the neck, in front of the Adam's apple, and are closely linked to

The parathyroid gland is accessed through an incision in the neck (A). Muscles and connecting tissues, or fascia, are cut open (B). The thyroid gland is exposed, and the superior (C) and inferior parathyroid glands are removed (D). The muscle layers are stitched, and the wound closed (E). (Illustration by GGS Information Services. Cengage Learning, Gale.)

the thyroid gland. The parathyroid glands regulate the balance of calcium in the body.

is approximately twice that of males. The incidence of parathyroidectomy rises after age 40.

### Purpose

Parathyroidectomy is usually performed to treat hyperparathyroidism (abnormal over-functioning of the parathyroid glands).

### Demographics

The number of parathyroidectomy procedures has risen due to routine measurement of calcium in the blood. Incidence rates vary between 25 and 50 per 100,000 persons. The number of procedures in females

### Description

The operation begins when an anesthesiologist administers **general anesthesia**. The surgeon makes an incision in the front of the neck where a tight-fitting necklace would rest. All of the parathyroid glands are identified. The surgeon then identifies the diseased gland or glands, and confirms the diagnosis by sending a piece of the gland(s) to the pathology department for immediate microscopic examination. The diseased glands are then removed, and the incision is closed and covered with a dressing.

## KEY TERMS

**Anesthesiologist**—A physician who specializes in anesthetizing persons for operations or other medical procedures.

**Ectopic parathyroid tissue**—Parathyroid tissue located in an abnormal place.

**Hyperparathyroidism**—Abnormal over-functioning of the parathyroid glands.

**Hypoparathyroidism**—Abnormal under-functioning of the parathyroid glands.

**Otolaryngologist**—A surgeon who treats people with abnormalities in the head and neck regions of the body.

**Recurrent laryngeal nerve**—A nerve that lies very near the parathyroid glands, and serves the larynx or voice box.

Parathyroidectomy patients usually stay overnight in the hospital after the operation. Some patients remain hospitalized for one or two additional days.

## Diagnosis/Preparation

Prior to the operation, the diagnosis of hyperparathyroidism should be confirmed using lab tests. Occasionally, physicians order computed tomography scans (**CT scans**), **ultrasound** exams, or **magnetic resonance imaging** (MRI) tests to determine the total number of parathyroid glands, and their location prior to the procedure.

Parathyroidectomy should only be performed when other non-operative methods have failed to control a person's hyperparathyroidism.

Preparation is similar to other surgical procedures requiring general anesthetic. The patient is not allowed any food or drink by mouth after midnight the night before surgery. He or she should ask the physician for specific directions regarding preparation for surgery, including food, drink, and medication intake.

## Aftercare

The incision should be watched for signs of infection. In general, no special **wound care** is required.

The calcium level is monitored during the first 48 hours after the operation by obtaining frequent blood samples for laboratory analysis.

Most individuals require only two or three days of hospitalization to recover from the operation. They

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

Parathyroidectomy is an operation performed most commonly by a general surgeon, or occasionally by an otolaryngologist, in the operating room of a hospital.

can usually resume most of their normal activities within one to two weeks.

## Risks

The major risk of parathyroidectomy is injury to the recurrent laryngeal nerve (a nerve that lies very near the parathyroid glands and serves the larynx or voice box). If this nerve is injured, the voice may become hoarse or weak.

Occasionally, too much parathyroid tissue is removed, and a person may develop hypoparathyroidism (under-functioning of the parathyroid glands). If this occurs, he or she will require daily calcium supplements.

In some cases, the surgeon is unable to locate all of the parathyroid glands, and cannot remove them in one procedure. A fifth or sixth gland may be located in an aberrant place such as the chest (ectopic parathyroid). If this occurs, the hyperparathyroidism may not be corrected with one operation, and a second procedure may be required to find all of the patient's remaining parathyroid gland tissue.

## Normal results

The surgery progresses normally if the diseased parathyroid glands are located and removed from the neck region.

## Morbidity and mortality rates

Hematoma formation (collection of blood under the incision) is a possible complication of any operative procedure. However, in procedures that involve the neck it is of particular concern because a rapidly enlarging hematoma can obstruct the airway.

Infection of the surgical incision may occur, as it may in any operative procedure, but this is uncommon in parathyroidectomy.

Before the function of the parathyroid gland was understood, people undergoing a **thyroidectomy** often

## QUESTIONS TO ASK THE DOCTOR

- What type of physician performs the surgery?
- Is the surgeon board certified in head and neck surgery?
- How many parathyroidectomy procedures has the surgeon performed?
- What is the surgeon's complication rate?
- Is there an alternative to surgery?
- What is the risk of complication?
- How will the body's function change after the surgery?

died due to the lack of calcium in their blood caused by removal of the parathyroid glands. This is not a problem today.

### Alternatives

There is no safe or reliable alternative to removal of the parathyroid glands for the treatment of hyperparathyroidism. Oral phosphates can lower serum calcium levels, but the long-term use of this approach is not well understood.

## Parentage testing

### Definition

Parentage testing (previously called paternity testing) refers to a variety of DNA tests used in an attempt to verify whether someone could possibly be the mother

or the father of a particular child. Parentage testing has two possible results: an individual can be definitively excluded as the parent, or an individual can be defined as having some degree of probability of being the parent.

In fact, neither paternity nor maternity can actually be definitively demonstrated through current tests. Instead, these tests provide information that a particular individual cannot be excluded as the child's parent. A mathematical model is then utilized to determine an estimate of the probability that, based on the results of the testing, a particular individual IS that child's parent. The probability is called the parentage index, and it uses DNA results, as well as situational information (where the alleged parent was at the time of the child's conception, comparison of the alleged parent's and the child's physical appearance) to generate a percent chance of parentage.

The first step in parentage testing involves collecting some type of DNA sample from the child in question, the known parent, and the alleged parent. Any type of biological tissue can be used for this testing. Most commonly, a testing sample is obtained either through a buccal (inside of the cheek) swab, or through blood testing. DNA is the genetic material stored inside the nucleus of every cell within the human body. The DNA can be extracted from the nucleus of the cells which have been procured in the testing sample for each individual. Laboratory testing then evaluates the known parent's DNA, and compares this to the child's DNA. The DNA of each individual is sequenced, and DNA sequences that match the known relationship are excluded. The remaining DNA sequences are then compared to DNA sequences of the alleged parent. This gives the examiners information on the probability that this individual is or is not capable of having parented the child, up to a probability of over 99.9%.

### Purpose

This test is performed to exclude the possibility that a particular individual could be the biological mother or father of a baby or child, or to provide evidence of probability that the individual might be the biological mother or father of a baby or child. These tests are often run when a mother is uncertain of her baby's paternity, to clarify child support issues, to clarify issues that may come up relative to an adoption, or in forensic medicine (medicine pertaining to a crime).

### Precautions

Parentage testing is not effected by illness, medications, activity level or diet. However, the test results can be affected by a recent blood transfusion. Therefore, if

## KEY TERMS

**Buccal**—The interior surface of the cheek.

**DNA**—Deoxyribonucleic acid; the substance within the nucleus of all human cells in which the genetic information is stored.

**Maternity**—Refers to the mother.

**Paternity**—Refers to the father.

blood is being used for the DNA testing, 90 days should elapse between a blood transfusion and parentage testing.

Patients who are taking anticoagulant medications should inform their healthcare practitioner prior to a blood draw, since this may increase their chance of bleeding or bruising after a blood test.

### Description

While blood testing is frequently performed for parentage testing, other types of tissue may be used to provide DNA samples appropriate for testing. This includes a buccal (inside of the cheek) swab, in which a cotton-swab like instrument is used to scrape a few of the cells from the inside of the cheek. In some cases, other types of biological tissue, bone, or teeth may be used for testing.

This test may be performed using blood drawn from a vein (usually one in the forearm), generally by a nurse or phlebotomist (an individual who has been trained to draw blood). A tourniquet is applied to the arm above the area where the needle stick will be performed. The site of the needle stick is cleaned with antiseptic, and the needle is inserted. The blood is collected in vacuum tubes. After collection, the needle is withdrawn, and pressure is kept on the blood draw site to stop any bleeding and decrease bruising. A bandage is then applied. Alternatively, a finger stick can be used to draw just a few drops of blood from a finger tip.

Because the results of parentage testing are frequently utilized in court or as evidence in legal decisions, there are very careful regulations on the way the samples are drawn, labeled, stored, and transported. It is crucial that the chain-of-custody of all samples is clearly delineated, and that all packaging is tamper-free and appropriately labeled. Individuals who are involved in the actual parentage case are restrained from being involved in the actual acts of either collecting or transporting the DNA-containing samples.

## Preparation

There are no restrictions on diet or physical activity, either before or after the testing.

## Aftercare

There is no aftercare necessary following a buccal swab.

As with any blood tests, discomfort, bruising, and/or a very small amount of bleeding is common at the puncture site. Immediately after the needle is withdrawn, it is helpful to put pressure on the puncture site until the bleeding has stopped. This decreases the chance of significant bruising. Warm packs may relieve minor discomfort. Some individuals may feel briefly woozy after a blood test, and they should be encouraged to lie down and rest until they feel better.

## Risks

Neither a buccal swab nor basic blood tests carry any significant risk.

## Results

One possible outcome of parentage testing is exclusion of the possibility that an individual has any chance whatsoever of being able to be genetically related as a parent to the child in question—this is referred to as a zero-percent probability. Positive proof of parentage can approach 99.9% probability that a particular individual could be a particular child's parent.

Parkinson's surgery see **Deep brain stimulation**

Parotid gland removal see **Parotidectomy**

# Parotidectomy

## Definition

Parotidectomy is the removal of the parotid gland, a salivary gland near the ear.

## Purpose

The parotid gland is the largest of the salivary glands. There are two parotid glands, one on each side of the face, just below and to the front of the ear. A duct through which saliva is secreted runs from each gland to the inside of the cheek.

The main purpose of parotidectomy is to remove abnormal growths (neoplasms) that occur in the parotid gland. Parotid gland neoplasms may be benign (approximately 80%) or malignant. Tumors may spread from other areas of the body, entering the parotid gland by way of the lymphatic system.

## Demographics

Benign parotid gland growths usually appear after the age of 40. Malignant growths most often affect women over the age of 60, while benign tumors affect both sexes equally. Cancer of the salivary glands accounts for only 1% of all cancers, and 7% of all head and neck cancers.

## Description

During surgery, two different areas of the parotid gland are identified: the superficial lobe and the deep lobe. Superficial parotidectomy removes just the superficial lobe, while total parotidectomy removes both lobes.

The patient is first placed under **general anesthesia** to ensure that no pain is experienced and that all muscles remain relaxed. An incision is made directly to the front or back of the ear and down the jaw line. The skin is folded back to expose the parotid gland. The various facial nerves are identified and protected during the surgery so as to avoid permanent facial paralysis or numbness. A superficial or total parotidectomy is then performed, depending on the type and location of the tumor. If the tumor has spread to involve the facial nerve, the operation is expanded to include parts of the bone behind the ear (mastoid) to remove as much tumor as possible. Before the incision is closed, a drain is inserted into the area to collect any leaking saliva, if a superficial parotidectomy was performed. The procedure typically takes from two to five hours to complete, depending on the extent of surgery and the skill of the surgeon.

Parotidectomy is a surgical procedure performed to remove cancerous tumors in the parotid gland, a salivary gland near the ear. Among the tumors seen in the parotid gland are lymphoma, melanoma, and squamous cell carcinoma. The illustration above shows the facial incision sites for this procedure. (Illustration by Electronic Illustrators Group. Cengage Learning, Gale.)

### Diagnosis/Preparation

A complete **physical examination** and medical history is performed, as are diagnostic tests to help

the surgeon better plan for the surgery. Some tests that may be performed include computed tomography (CT) scan, **magnetic resonance imaging** (MRI),

## KEY TERMS

**Fistula**—An abnormal opening or duct through tissue that results from injury, disease, or other trauma.

**Salivary glands**—Three pairs of glands that secrete into the mouth and aid digestion.

and fine-needle aspiration biopsy (using a thin needle to withdraw fluid and cells from the growth).

## Aftercare

After surgery, the patient will remain in the hospital for one to three days. The incision site will be watched closely for signs of infection and heavy bleeding (hemorrhage). The incision site should be kept clean and dry until it is completely healed. If the patient has difficulty smiling, winking, or drinking fluids, the physician should be contacted immediately. These are signs of facial nerve damage.

## Risks

There are a number of complications that are associated with parotidectomy. Facial nerve paralysis after minor surgery should be minimal. After major surgery, a graft is attempted to restore nerve function to facial muscles. Salivary fistulas can occur when saliva collects in the incision site or drains through the incision. Recurrence of cancer is the single most important consideration for patients who have undergone parotidectomy. Long-term survival rates are largely dependent on the tumor type and the stage of tumor development at the time of the operation.

Other risks include hematoma (collection of blood under the skin) and infection. The most common long-term complication of parotidectomy is redness and sweating in the cheek, known as Frey's syndrome. Rarely, paralysis may extend throughout all the branches of the facial nervous system.

## Normal results

Although some facial numbness or weakness is normal immediately following parotidectomy, these symptoms usually subside within a few months, with most patients regaining full function within one year. Return of a benign tumor is very rare.

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

Parotidectomy is performed in a hospital operating room, usually by an otolaryngologist, a medical doctor who specializes in the treatment of diseases that affect the ear, nose, throat, and other structures of the head and neck.

## Morbidity and mortality rates

There is a 25–50% risk of temporary facial weakness following parotidectomy, and a 1–2% risk of permanent weakness. Frey's syndrome may be experienced by up to 90% of patients to some extent and causes perspiration on that side of the face with eating. There is very little or no risk of mortality associated with the surgery. The survival rate of malignant parotid gland tumors depends on their size, location, extension, and if metastasis has occurred. The 10-year survival rate ranges from 32% to 83%.

## Alternatives

A benign parotid neoplasm may be managed expectantly (i.e., adhering to a period of watchful waiting) so that the growth is of a larger size before it is removed (the risk of facial nerve damage increases with each subsequent parotidectomy). There is generally no alternative to surgical treatment of parotid gland neoplasms, although radiation therapy may be recommended after the procedure in the case of malignant tumors.

## Partial thromboplastin time

### Definition

The partial thromboplastin time (PTT) test is a blood test that is done to investigate bleeding disorders and to monitor patients taking an anticlotting drug (heparin).

### Purpose

#### Diagnosis

Blood clotting (coagulation) depends on the action of substances in the blood called clotting factors. Measuring the partial thromboplastin time helps to assess which specific clotting factors may be missing or defective.

#### Monitoring

Certain surgical procedures and diseases cause blood clots to form within blood vessels. Heparin is used to treat these clots. The PTT test can be used to

monitor the effect of heparin on a patient's coagulation system.

### Precautions

Certain medications besides heparin can affect the results of the PPT test. These include antihistamines, vitamin C (ascorbic acid), **aspirin**, and chlorpromazine (Thorazine).

### Description

When a body tissue is injured and begins to bleed, it starts a sequence of clotting factor activities called the coagulation cascade, which leads to the formation of a blood clot. The cascade has three pathways: extrinsic, intrinsic, and common. Many of the thirteen known clotting factors in human blood are shared by both pathways; several are found in only one. The PTT test evaluates the factors found in the intrinsic and common pathways. It is usually done in combination with other tests, such as the prothrombin test, which evaluate the factors of the extrinsic pathway. The combination of tests narrows the list of possible missing or defective factors.

Heparin prevents clotting by blocking certain factors in the intrinsic pathway. The PTT test allows a doctor to check that there is enough heparin in the blood to prevent clotting, but not so much as to cause bleeding. The test is done before the first dose of heparin or whenever the dosage level is changed; and again when the heparin has reached a constant level in the blood. The PTT test is repeated at scheduled intervals.

The PTT test uses blood to which a chemical has been added to prevent clotting before the test begins. About 5 mL of blood are drawn from a vein in the patient's inner elbow region. Collection of the sample takes only a few minutes. The blood is spun in a centrifuge, which separates the pale yellow liquid part of blood (plasma) from the cells. Calcium and activating substances are added to the plasma to start the intrinsic pathway of the coagulation cascade. The partial thromboplastin time is the time it takes for a clot to form, measured in seconds.

The test can be done without activators, but they are usually added to shorten the clotting time, making the test more useful for monitoring heparin levels. When activators are used, the test is called activated partial thromboplastin time or APTT.

Test results can be obtained in less than one hour. The test is usually covered by insurance.

## Preparation

The doctor should check to see if the patient is taking any of the medications that may influence the test results. If the patient is on heparin therapy, the blood sample is drawn one hour before the next dose of heparin.

## Aftercare

Aftercare includes routine care of the puncture site. In addition, patients on heparin therapy must be watched for signs of spontaneous bleeding. The patient should not be left alone until the doctor or nurse is sure that bleeding has stopped. Patients should also be advised to watch for bleeding gums, bruising easily, and other signs of clotting problems; to avoid activities that might cause minor cuts or bruises; and to avoid using aspirin.

## Risks

The patient may develop a bruise or swelling around the puncture site, which can be treated with moist warm compresses. People with coagulation problems may bleed for a longer period than normal.

## Normal results

Normal results vary based on the method and activators used. Normal APTT results are usually between 25–40 seconds; PTT results are between 60–70 seconds. APTT results for a patient on heparin should be 1.5–2.5 times normal values. An APTT longer than 100 seconds indicates spontaneous bleeding.

## Abnormal results

Increased levels in a person with a bleeding disorder indicate a clotting factor may be missing or defective. Further tests are done to identify the factor involved. Liver disease decreases production of factors, increasing the PTT.

Low levels in a patient on heparin indicate too little heparin is in the blood to prevent clots. High levels indicate too much heparin is present, placing the person at risk of excessive bleeding.

## Morbidity and mortality rates

Morbidity rates are excessively miniscule. The most common problems are minor bleeding and bruising. Since neither are reportable events, morbidity can only be estimated. Mortality is essentially zero.

## KEY TERMS

**Activated partial thromboplastin time**—Partial thromboplastin time test that uses activators to shorten the clotting time, making it more useful for heparin monitoring.

**Clotting factors**—Substances in the blood that act in sequence to stop bleeding by forming a clot.

**Coagulation**—The process of blood clotting.

**Coagulation cascade**—The sequence of biochemical activities, involving clotting factors, that stop bleeding by forming a clot.

**Common pathway**—The pathway that results from the merging of the extrinsic and intrinsic pathways. The common pathway includes the final steps before a clot is formed.

**Extrinsic pathway**—One of three pathways in the coagulation cascade.

**Heparin**—A medication that prevents blood clots.

**Intrinsic pathway**—One of three pathways in the coagulation cascade.

**Partial thromboplastin time**—A test that checks the clotting factors of the intrinsic pathway.

**Plasma**—The fluid part of blood, as distinguished from blood cells.

## Alternatives Resources

There are no alternatives to a partial thromboplastin time.

## Precautions

The only precaution needed is to clean the venipuncture site with alcohol.

## Side effects

The most common side effects of a partial thromboplastin time test are minor bleeding and bruising.

Patent ductus arteriosus repair see **Heart surgery for congenital defects**

## Patent urachus repair

### Definition

Patent urachus repair is surgery to correct a urachus (a tube that connects the fetal bladder to the umbilical cord) that fails to close after birth.

### Purpose

A patent urachus is an anomaly, and repair is recommended for these defects occurring at birth.

### Demographics

The condition occurs three times more often in male infants than in females.

### Description

As fetal development progresses, the urachus, a tube that can measure from 1.2–3.9 in (3–10 cm) long and 0.3–0.4 in (8–10 mm) in diameter, forms, extending from the front dome of the bladder to the umbilicus. Following birth, the tube, adjacent to the umbilical ligaments, closes and itself becomes ligament. Should this closure fail, it may result in several types of urachal remnants. If the urachus remains completely open, it is known as a patent urachus. This type of abnormality makes up 50% of all urachal anomalies.

If the urachus remains open all the way to the bladder, there is the danger that bacteria will enter the bladder through the open tube and cause infection. For this reason, the patent urachus of the infant must be removed.

### Diagnosis/Preparation

This anomaly occurs as an isolated event or in association with prune-belly syndrome, in which there is continuous drainage of urine from the umbilicus. If urine freely discharges through the umbilicus, the patent urachus is rarely found. It should be suspected, however, if a local cord is enlarged and affected with edema, or is slow to slough normally. The condition customarily is diagnosed in infants.

The child is given a general anesthetic, after which an incision is made in the lower abdomen.

## Patent urachus repair

A patent urachus is an abnormal opening from the bladder to the umbilicus, which is retained from fetal life (A). To repair it, an incision is made in the baby's abdomen (B). The patent urachus is removed (C), and the opening to the bladder is closed (D). (Illustration by GGS Information Services. Cengage Learning, Gale.)

### Aftercare

Surgery for patent urachus repair may require several days' hospitalization, during which infants can be fed as normal.

### Risks

Risks are the same as for those patients receiving any anesthesia: a reaction to medication and/or

breathing problems. There is also the risk of bladder infection or bladder leaks. In the latter case, a catheter is put in place until the bladder heals.

### Normal results

The outcomes of patent urachus repair in infants are excellent, as a rule, and most children recover rapidly.

## KEY TERMS

**Adenocarcinoma**—A malignant tumor that originates in the membranous tissue that serves as the covering of a gland.

**Anterolateral**—Situated in front and to the side.

**Patency**—The state of being open or unblocked.

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

Patent urachus repair is performed by the pediatric surgeon in a hospital setting.

## Morbidity and mortality rates

Patent urachal anomalies do not usually cause significant morbidity or mortality. However, adenocarcinoma has been reported in adults with urachal remnants, presumably from chronic inflammation and infection. Patency is noted in only 2% of adults.

## Alternatives

Sometimes more conservative treatment than surgery is advised, with radical excision reserved for persistent or recurring cases. Because the urachus may not completely close at birth, but may close within the first few months of the infant's life, observation may be advised before moving forward with surgery.

## QUESTIONS TO ASK THE DOCTOR

- Is it advisable to put off surgery during the first few months of the child's life and see if the urachus will close on its own?
- What effects will surgery have on a newborn?

## Patient-controlled analgesia

### Definition

Patient-controlled analgesia (PCA) is a means for the patient to self-administer **analgesics** (pain medications) intravenously by using a computerized pump, which introduces specific doses into an intravenous line.

### Purpose

The purpose of PCA is improved pain control. The patient receives immediate delivery of pain medication without the need for a nurse to administer it. The patient controls when the medication is given. More importantly, PCA uses more frequent but smaller doses of medication, and thus provides more even levels of medication within the patient's body. Syringe-injected **pain management** by a nurse requires larger doses of medication given less frequently. Larger doses peak shortly after administration, often causing undesirable side effects such as nausea and difficulty in breathing. Their pain-suppressing effects also often wear off before the next dose is scheduled.

### Description

PCA uses a computerized pump, which is controlled by the patient through a hand-held button that is connected to the machine. The pump usually delivers medications in small regular doses, and it can be programmed to issue a large initial dose and then a steady, even flow. The PCA pump can deliver medicine into a vein (intravenously, the most common method), under the skin (subcutaneously), or between the dura mater and the skull (epidurally).

When the patient feels the need for medication, the patient presses a button similar to a nurse call button. When this button is pressed, some sound (usually a beep) is heard, indicating that the pump is working properly and that the button was pressed correctly. The pump delivers the medication through an intravenous line, a plastic tube connected to a needle

## KEY TERMS

**Analgesia**—A medicine that relieves pain.

**Epidural**—Between the vertebrae and the dura mater of the spinal cord. Analgesia is introduced into this space anywhere along the spinal column.

**Intravenous**—Within a vein, usually meaning something introduced into a vein such as an injection.

**Lockout time**—The minimum amount of time (usually expressed in minutes) after one dose of pain medication on demand is given before the patient is allowed to receive the next dose on demand.

**Opioid**—A synthetic drug resembling opium or alkaloids of opium.

**Respiratory depression**—Decreased rate (number of breaths per minute) and depth (how much air is inhaled with each breath) of breathing.

**Subcutaneous**—Under the skin, as in an injection under the skin.

inserted into a vein. Glucose and other medications can also be administered through intravenous lines, along with analgesics.

The medications most commonly used in PCA pumps are synthetic, opium-like pain-relievers (opioids), usually morphine and meperidine (Demerol).

The pump may be set to deliver a larger initial dose of the prescribed drug. The health-care provider sets the pump to deliver a specified dose, determined by the physician, on demand with a lockout time (for example, 1 mg of morphine on demand, but not more frequently than one dose every six minutes). If the patient presses the button before six minutes have elapsed, the pump will not dispense the medication. The pump also generates a record that the health personnel can access. An around-the-clock, even dose may also be set. The practitioner sets a total limit for an hour (or any other period) that takes into account the initial dose, the demand doses, and the around-the-clock doses. The pump's internal computer calculates all these amounts, makes a record of the requests it received and those it refused, and also keeps inventory of the medication being administered, which warns the staff when the supply is getting low.

An example of how a nurse might program the pump might be for a patient who has a prescription for

a maximum of 11 mg of morphine an hour. The nurse sets the machine to deliver 1 mg at the beginning of the hour, and 1 mg on demand with a six-minute lockout. There are 10 six-minute periods in an hour, so the patient can request and receive 10 mg over that hour.

Using a PCA pump requires that the patient understand how the system works and has the physical strength to press the button. Therefore, PCA should not be offered to patients who are confused, unresponsive, or paralyzed. Patients with neurologic disease or head injuries in whom narcotics would mask neurologic changes are not eligible for PCA. Patients with poor kidney or lung function are usually not good candidates for PCA, unless they are monitored very closely.

PCA may be used by children as young as seven years old. It has proven safe and successful in such children in the control of postoperative pain, sickle-cell pain, and pain associated with bone-marrow transplantation. In all cases, the child should manage the PCA pump himself or herself. As morphine can slow breathing in young patients, the blood oxygen levels of children must be closely monitored.

In addition, PCA has been found safe for nursing mothers after a **cesarean section**. Very small amounts of morphine do pass into the milk of breastfeeding mothers, but it has not proved harmful to infants.

## Preparation

When preparing for PCA, the nurse must assess the patient to determine whether PCA is appropriate and then must set the total dose and the timing of the doses as prescribed by the physician. Since there is only a small amount of drug administered (3,000 doses at 10 mg each weigh less than 1 oz total), it is not sufficient fluid to keep the tubing and the needle from clogging and the contents from coagulating. Therefore, the drug must be put in a solution (flush solution) that will flow through the tube and needle easily, and permit rapid administration. The flush solution also keeps the line open for administration of other medications or in case the patient has a reaction to the pain medications. For example, a patient may have a reaction to morphine and would need counteractive medication immediately. The flush solution can also keep the patient from becoming dehydrated. In addition, many painkillers that are prescribed (such as morphine sulfate) are solid crystals at room temperature and need to be dissolved in some fluid to be absorbed by the body.

When entering the settings into the PCA system, the nurse must pay close attention to the physician's orders to ensure that the correct medication is used, that the concentration of the drug in the flushing solution is correct, that the dose of the drug itself is correct, that the lockout time is appropriate, and that the total hourly limit is properly entered into the pump's computerized controls. To eliminate the risk of incorrect programming, many institutions have adopted policies that require verification by a registered nurse (RN) for all programming. That is, everything must be checked by two nurses, and both must sign the written record.

Another important aspect of PCA is patient education. The settings on the PCA pump must be explained to patients so that they understand how and when medications will be available. The nurse should observe patients as they first start using the button, should ensure that the equipment is functioning properly, and be clear that the patients understand their role in the process and are carrying it out correctly.

Whenever opium-like painkillers are administered to the elderly patient, it must be remembered that older adults may be more susceptible to the side effects of narcotics because the heart, liver, and kidneys of the elderly function less efficiently than those of younger patients. The elderly may also clear the narcotic out of their system at a slower pace. If the pump's timing device is calibrated for a younger person's rate of elimination, the elderly patient could accidentally receive an overdose. Doses for such elderly patients should be calculated more conservatively.

### Normal results

The goal of patient-controlled analgesia is managed pain control, enhanced by a stable and constant level of the pain medication in the body. The patient is able to rest better and breathe more deeply. Since the patient is comfortable, he or she is more able to participate in activities that would enhance recovery. PCA also gives the patient in the hospital some control in an unfamiliar and uncomfortable situation. When administered properly, and with watchful assessment by health-care providers, PCA can be a safe alternative to traditional methods of relieving pain.

Interestingly enough, studies have shown that when patients control their pain medication, most use less medication overall than patients who have nurse-administered painkillers.

### Risks

Problems that may occur with PCA include allergic reactions to the medications and adverse side effects such as nausea, a dangerous drop in the rate and effectiveness of breathing, and excessive sedation. The PCA device must be monitored frequently to prevent tampering. Even sophisticated devices that monitor themselves and sound an alarm should be checked often, since no machine is perfect. Ineffective pain control must be assessed to determine whether the problem stems from inadequate dosage or from inability, or unwillingness, of the patient to carry out his or her own pain management.

## Patient confidentiality

### Definition

Confidentiality is the right of an individual to have personal, identifiable medical information kept private. Such information should be available only to the physician of record and other health care and insurance personnel as necessary. As of 2003, patient confidentiality was protected by federal statute.

### Purpose

The passage of federal regulations (the Health Insurance Portability and Accountability Act of 1996) was prompted by the need to ensure privacy and protection of personal records and data in an environment of electronic medical records and third-party insurance payers.

### Description

Patient confidentiality means that personal and medical information given to a health care provider will not be disclosed to others unless the individual has given specific permission for such release.

Because the disclosure of personal information could cause professional or personal problems, patients rely on physicians to keep their medical information private. It is rare for medical records to remain completely sealed, however. The most benign breach of confidentiality takes place when clinicians share medical information as case studies. When this data is published in professional journals the identity of the patient is never divulged, and all identifying data is either eliminated or changed. If this confidentiality is breached in any way, patients may have the right to sue.

The greatest threat to medical privacy, however, occurs because most medical bills are paid by some form of health insurance, either private or public. This makes it difficult, if not impossible, to keep information truly confidential. Health records are routinely viewed not only by physicians and their staffs, but by the employees of insurance companies, medical laboratories, public health departments, researchers, and many others. If an employer provides health insurance, the employer and designated employees may have access to employee files.

The Health Insurance Portability and Accountability Act (HIPAA) of 1996 requires all professionals and organizations to guard the privacy of their patients and customers. Individuals must provide written consent for any and all releases of medical or

## KEY TERMS

**HIPAA**—Health Insurance Portability and Accountability Act of 1996.

**Joint Commission on Accreditation of Healthcare Organizations (JCAHO)**—The accrediting organization that evaluates virtually all U.S. health care organizations and programs. Accreditation is maintained with onsite surveys every three years; laboratories are surveyed every two years.

health-related information. Employees at all levels are required to maintain confidentiality. Similar policies have been in place for some time. This was a requirement of the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) to maintain accreditation. All confidentiality releases must identify the types of information that can be released, the people or groups that have been permitted access to the information, and limit the length of time for which the release is valid.

Before the enactment of HIPAA, despite having voluntary safeguards, patient confidentiality had eroded with the almost-complete dominance of health-maintenance organizations and other types of third-party payers. Confidentiality is essential for a good relationship between patient and practitioner, whose duty to keep information private stems from the Hippocratic Oath. If personal information is disseminated without the patient's permission, it can erode confidence in the medical profession and expose health care professionals to legal action.

Physicians are increasingly being sued by patients whose information has been released without their permission. Even though the plaintiffs do not always prevail, the costs of legal action are burdensome to both sides.

Each state and the federal government have enacted laws to protect the confidentiality of health care information generally, with particular attention paid to information about communicable diseases and mental health. For example, through the 1960s substance and alcohol abuse were treated as mental illnesses, with patient confidentiality determined by the laws in each state, since at the time the state was responsible for mental health care and treatment.

In the early 1970s, however, the rising numbers of those needing substance abuse treatment came to the attention of the federal government, because drug-related activity, including the treatment for substance

abuse, could be the basis for criminal prosecution on a federal level. Congress concluded that this might stop individuals needing treatment from seeking it. HIPAA was enacted to provide a strict confidentiality law and limit disclosure of information that could reveal a patient's identity.

Confusion ensued when practitioners who were treating substance abusers were required to follow two practices for patient confidentiality. One set of requirements was mandated by the state. The federal government dictated the other. With the varying degrees of protection provided by state mental health laws, the confusion increased. While all states specify exceptions to confidentiality, few have spelled out the necessary elements of valid consent for disclosure of mental health information. Some states presently allow disclosure of the following types of mental health information without patient consent:

- to other treatment providers
- to health care services payers or other sources of financial assistance to the patient
- to third parties that the mental health professional feels might be endangered by the patient
- to researchers
- to agencies charged with oversight of the health care system or the system's practitioners
- to families under certain circumstances
- to law enforcement officials under certain circumstances
- to public health officials

Prior to 2003, providers had become increasingly concerned that these exceptions are not addressed uniformly, particularly when providers and payers conducted business across state lines. This resulted in open-ended disclosures that specify neither the parties to whom disclosure is to be made nor the specific information allowed to be revealed. Since 2003, implementation of HIPAA requirements have rectified this problem.

Both the ethical and the legal principles of confidentiality are rooted in a set of values regarding the relationship between caregiver and patient. It is essential that a patient trust a caregiver so that a warm and accepting relationship may develop. This is particularly true in a mental health treatment.

### Normal results

The Health Insurance Portability and Accountability Act of 1996 was enacted to address the issue of patient confidentiality. Full implementation of HIPAA regulations began in April 2003. If individuals and organizations having patient data adhere to the

requirements of HIPAA, patient confidentiality will be enhanced.

HIPAA provides a uniform set of guidelines that apply to all providers and organizations. HIPAA requirements are not affected by state boundaries.

## Patient rights

### Definition

Patient rights encompass legal and ethical issues in the provider-patient relationship, including a person's right to privacy, the right to quality medical care without prejudice, the right to make informed decisions about care and treatment options, and the right to refuse treatment.

### Purpose

The purpose of delineating patient rights is to ensure the ethical treatment of persons receiving medical or other professional health care services. Without exception, all persons in all settings are entitled to receive ethical treatment.

### Description

Many issues comprise the rights of patients in the medical system, including a person's ability to sue a health plan provider; access to emergency and specialty care, diagnostic testing, and prescription medication without prejudice; confidentiality and protection of patient medical information; and continuity of care.

Health care reform led to an emergence of health maintenance organizations (HMOs) and other managed health care plans. The rapid change in medical care moved health care decision making from medical professionals to business entities, a move many consider to be detrimental to the health care industry in general.

Establishing a patient's bill of rights has been the response to this concern. The Bipartisan Patient Protection Act of 2001 has been signed into law.

At issue, besides basic rights of care and privacy, is the education of patients concerning what to expect of their health care facility and its providers. These basic rights include the right to:

- participate in the development and implementation in the plan of care
- be treated with respect and dignity
- be informed about condition, treatment options, and the possible results and side effects of treatment
- refuse treatment in accordance with the law, and receive information about the consequences of refusal
- quality health care without discrimination because of race, creed, gender, religion, national origin, or source of payment
- privacy and confidentiality, which includes access to medical records upon request
- personal safety
- know the identity of the person treating the patient, as well as any relationship between professionals and agencies involved in the treatment
- informed consent for all procedures
- information, including the medical records by the patient or by the patient's legally authorized representative and hospital charges, except for Medicaid and general assistance
- consultation and communication
- complain or compliment without the fear of retaliation or compromise of access or quality of care

Patients are expected to meet a fair share of responsibility by following the plan of care, providing complete and accurate health information, and communicating comprehension of instructions on procedures and treatment. The patient is further responsible for consequences of refusal of treatment, of not following the rules and regulations of a hospital, and of not being considerate of others' rights. The patient is also responsible for providing assurance that financial obligations of care are met.

The American Hospital Association provides an informal bill of rights for patients who are hospitalized, which informs patients that they have the right to refuse any procedure or medication that is prescribed, and that states that full information should be provided by the attending physician if the patient has expressed doubts or concerns.

Persons United Limiting Substandards and Errors in Health Care (PULSE), a non-profit organization concerned with patient education and improving communication within the health care system, encourages the partnership of health care professionals and patients. A patient who is educated about his or her own medical condition can work together with health care providers regarding treatment decisions.

New federal privacy rules, beyond the proposed patient bill of rights, give patients additional control over private medical information. Patients have the right to examine their own medical records and to amend them if necessary. In practice, medical personnel have often been reluctant to part with patient records, even when requested by the patients themselves. While health care providers and patients assume that medical records are private, the widespread use of computer transmissions opens the potential for seriously compromising **patient confidentiality**. Regulations recently imposed by the federal government are aimed at protecting patient records by creating limits on the methods in which medical information is shared. Direct authorization from a patient must be gained before information may be released. Criminal and civil penalties may be imposed for a privacy violation. Intentional disclosure of private information can bring a \$50,000 fine and a one-year prison term. Penalties for selling medical information are higher. These rules became enforceable in 2003.

## Alternatives

Not all individuals or organizations agree with the new regulations. Some complain that they are too restrictive, while others maintain that they are not restrictive enough. The Joint Commission on Accreditation of Healthcare Organizations (JCAHO) cites complexity and cost factors as major problems, and that the full extent of the impact caused by the ruling was not adequately considered when it passed in 2003. The government estimated that it will cost taxpayers \$17.6 billion over 10 years to comply with the privacy regulations. Critics of the regulations imply that the cost will be more than triple the estimate, and that billable hours for attorneys specializing in the complexities of the regulations will skyrocket, thus resulting in even higher costs of patient care.

## Pectus excavatum repair

### Definition

Pectus excavatum repair, also called “funnel chest repair” or “chest deformity repair,” is a type of surgery performed to correct pectus excavatum, a deformity of the front of the chest wall with depression of the breastbone (sternum) and rib (costal) cartilages. It is sometimes associated with Marfan or Poland syndrome.

### Purpose

The chest consists of the rib cage and sternum, which protect the upper-abdominal cavity and its contents. Pectus excavatum, also called “funnel chest” or “depressed sternum” is a deformity that is usually diagnosed shortly after birth. In some people, it is not visible until they are older. The exact cause is not known, but it is believed to be due to overgrowth of the rib cartilage connected to the sternum, which connects to the sternum being pushed backward toward the spine. Most people have no symptoms, but if the breastbone is pushed back far enough, heart and lung function may be affected. The purpose of pectus excavatum repair surgery is to correct the deformity to improve physical appearance, posture, and breathing.

### Demographics

In the United States, pectus excavatum is the most common chest wall deformity observed in children, occurring more commonly in boys than in girls. Pectus excavatum tends to run in families. The funnel chest usually progresses as the child grows, often showing a

## KEY TERMS

**Marfan syndrome**—A condition occasionally associated with chest wall deformities, in which the patients have a characteristic tall, thin appearance, and cardiac and great vessel abnormalities.

**Pectus carinatum**—A chest wall deformity characterized by a protrusion of the sternum.

**Pectus excavatum**—A chest wall deformity in which the chest wall takes on a sunken appearance.

**Poland syndrome**—A condition associated with chest wall deformities in which varying degrees of underdevelopment of one side of the chest and arm may occur.

**Sternum**—The breastbone. It connects to ribs one through seven on either side of the chest.

dramatic deterioration during the puberty growth spurt.

Pectus excavatum repair is technically easiest to perform in preadolescent children, and the recovery is faster. However, almost half of the patients undergoing the operation are teenagers. Repair is rarely performed on children under eight years of age. In recent years, a large number of adults over the age of 21 years have undergone repair with equally good results as those observed with children.

### Description

Pectus excavatum repair is always performed with the patient under **general anesthesia**. An epidural catheter is inserted for the management of pain after the operation. The surgeon makes two incisions over the sternum, on either side of the chest, for insertion of a curved steel bar or strut under the sternum. He or she proceeds to remove the deformed cartilages. The rib lining is left in place to allow renewed cartilage growth. The sternum is then repositioned, and the metal strut is placed behind it and brought out through the muscles and skin for future attachment to a brace, which will stay in place six to 12 weeks. The metal strut is fixed to the ribs on either side, and the incisions are closed and dressed. A small steel grooved plate may be used at the end of the bar to help stabilize and fix the bar to the rib. A blood **transfusion** is not required during surgery. The surgeon may insert a temporary chest tube to re-expand the lung if the lining of the lung is entered.

A variety of surgical procedures are available to repair pectus excavatum.

### *Nuss procedure*

A common technique is the Nuss procedure, developed in 1987 by Dr. Donald Nuss, a pediatric surgeon at Children's Hospital of the The King's Daughters and Eastern Virginia Medical School in Norfolk, Virginia. The procedure is minimally invasive, and results in very little blood loss and short recovery times.

### *Leonard procedure*

Another surgical approach that drastically reduces the time required for surgery is the Leonard procedure, developed by Dr. Alfred Leonard, a Minneapolis thoracic and pediatric surgeon. This operation does not violate the chest, and is combined with a bracing technique.

## Diagnosis/Preparation

A pediatrician diagnoses pectus excavatum after observing a child when he or she inhales, exhales, and rests. The pediatrician also calculates the depth of the chest from front to back using x rays of the chest to determine whether the diameter is shorter than average, as is the case with funnel chest. The heart is usually larger and displaced to the left. The pediatrician also evaluates lung capacity using **exercise** tests and lung scans that can reveal mismatched lungs.

Other diagnostic tests may include:

- Electrocardiogram (ECG or EKG). This test records the electrical activity of the heart, and shows abnormal rhythms (arrhythmias or dysrhythmias).
- Echocardiogram (echo). This test evaluates the structure and function of the heart by using sound waves recorded on an electronic sensor that yields a moving picture of the heart and its valves.

Before surgery, a bone density test is performed to ensure that the patient does not have soft bones that would deform again right after the surgery. After a complete **health history** is taken, a patient whose condition is considered severe enough to warrant surgery is sent for a CT scan and further evaluation of his or her pulmonary function.

Because of the great variability of pectus excavatum among those who have it, custom-made bars (or braces) must be used. The brace is a light vest to which the deformity-correcting wire will be attached at surgery. Patients are fitted with the brace prior to surgery.

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

Pectus excavatum repair is performed in a hospital by experienced thoracic surgeons who specialize in pectus excavatum repair.

## Aftercare

Usual recovery time in the hospital is four to five days. Attention is paid to post-operative **pain management**. The patient is encouraged to breathe deeply, and receives assistance with movement (to avoid dislodging the bar). After discharge, the patient slowly resumes a normal, but restricted, activity level. Most children are able to return to school in two to three weeks, with exercise restrictions for six weeks (no physical education classes, heavy lifting, or athletics).

The pectus excavatum support bar is removed under general anesthesia two to four years after insertion, usually on an outpatient basis. In most cases, patients are able to leave the hospital within one to two hours after bar removal.

## Risks

Risks associated with pectus excavatum repair include those normally associated with the administration of anesthesia (such as adverse reactions to medications and breathing problems), and risks associated with any surgery (such as bleeding and infection). Specific pectus excavatum surgery risks may include lung collapse (pneumothorax) and the recurrence of the funnel chest. Bar displacement may occasionally require repositioning.

## Normal results

Pectus excavatum repair, in almost all instances, restores the ability of patients to participate in full activities, even strenuous activities and athletics. Also, there is a marked improvement in the patient's self image.

## Morbidity and mortality rates

According to the National Institutes of Health (NIH), excellent results (95–98%) are reported over a lengthy follow-up time of 25 years. Long-term follow-up (over 15 years) shows that the Nuss procedure provides excellent results with less than 5% recurrence of the deformity after the bar is removed.

## QUESTIONS TO ASK THE DOCTOR

- Can exercises correct pectus excavatum?
- How is pectus excavatum surgery performed?
- Should everyone with pectus excavatum have surgery?
- What surgical procedures does the doctor use?
- How many pectus excavatum surgeries does the physician perform each year?

### Alternatives

Mild cases of pectus excavatum may respond to an exercise and posture physiotherapy program. Many patients with rounded shoulders and a slouching posture have benefited from these techniques, with or without additional surgical correction. However, body-building exercises usually result in worsening of cosmetic appearance due to the enhancement of the pectoral muscles.

## Pediatric concerns

### Definition

Pediatric concerns are those issues that are unique to the care of children when surgery and hospitalization are involved.

### Description

Children are not just little adults. When dealing with children medically, it is important to keep in mind the stage of their physical growth and development; their emotional development; and their maturity level. There are many different kinds of pediatric surgeries and procedures. A pediatric hospital is designed around the special needs of children and their families. All of the staff, including doctors (pediatric surgeons, pediatric anesthesiologists, pediatric radiologists), nurses, and technical support, have special training in pediatrics. Children's hospitals have specific expertise in pediatric problems and special programs for children who are ill or injured.

### Helping a child prepare for surgery

When parents are helping their child prepare for surgery, it is important to realize that, no matter how mature the child may act, he or she still needs to be treated differently than adults. Some children find it comforting to know exactly what will happen, when, and how, all in great detail. Others do not want much detail. They may need just an overview of what to expect, keeping just one step ahead of what will be done to them. The particular level of a child's development will determine the specific concerns.

For example, the biggest fear for infants and toddlers is being away from their parents. Parents should stay with the child as much as possible, and ensure that basic needs (such as eating, play, or sleeping) are met, both at home and in the hospital. Preschoolers also fear being away from the parents, but, additionally, they see hospitalization as a punishment and fear

## KEY TERMS

**Child life specialist**—A person who has had specific training in the care of children, including understanding growth and development specific to each age range and how to talk to children of different ages.

**Pediatrics**—The medical specialty of caring for children.

**Separation anxiety**—A fear of being separated from a parent or loved one; a normal developmental process, occurring at certain points in a young child's life.

bodily harm. In this case, parents should, again, stay with the child as much as possible, and start talking to them at home about the coming operation to help reassure them. For the hospital stay, parents should bring the child's favorite blanket and/or toys, pictures from home, and maybe music tapes.

For school-age children, the biggest fears are needles and pain. Parents can help by giving them information about their body and how it works, and vaguely explain that the doctor will fix them, but parents should not use language like "cut, incision, open you up, make a hole, etc." To make the hospital feel more familiar, parents can bring pictures and music tapes and/or videos from home. By adolescence, children are worried about the loss of independence, being separated from their peers, and being different (i.e., a change in their appearance). For teenagers at this stage of development, it is extremely important to explain an illness or hospitalization to them in terms that they can understand, using examples to which they can relate, and allow them to be involved in decisions, if possible. The parents should encourage them to ask questions.

### *What to expect at the hospital*

Being in a hospital and undergoing surgery is scary and stressful for a child. Hospitalization disrupts their normal routines. If the staff behaves in a trusting, nurturing way, the child may become comfortable enough to return to some normal behaviors. Trust is important to all ages of children. If a procedure will hurt, it is important to be honest and let them know what to expect. Children can only learn to trust the staff if the staff is honest with them and treats them with respect.

Books and videos developed for children that explain about going to the hospital can be helpful. Some hospitals provide programs for children to come and visit before the hospitalization, so that children will

already be familiar with the hospital environment when they are admitted. Play is a child's way of expressing emotion, especially under difficult situations. Play can serve as a distracter as well as a means by which surgery and hospitalization can be explained to children. Dolls or stuffed animals can be used to walk young children through what they will be experiencing. Hospital play areas will often have toys that represent hospital equipment, so that a procedure can be explained with the use of props. For example, there may be pretend casts and **bandages** that a child can put on a stuffed animal. How children play can also serve as an insight for parents and staff as to understand how their children are feeling about what is happening to them. As children express their concerns through play, parents and staff can then address those concerns. Play is therapeutic for children, helping them feel safer in an unfamiliar environment, and should be considered an essential element in preparing for a child's hospital stay. Play areas help to make a strange place feel comfortable, both for the child as well as for the parents. Play areas also provide a relaxed area for parents to be with their child, a friendly home-like environment where nurturing can take place.

Unfortunately, some surgeries are not planned. Emergency situations are always more stressful, both because they are unexpected and because they are often more serious. Children take their cue on how to behave from those around them. When parents are noticeably concerned, children's anxiety levels rise. Parents should remain as calm as possible to be fully present for their children.

Parents should expect to be able to be with their children most of the time. For most day surgeries, parents can stay with their child until he or she is asleep, and then can be waiting in the **recovery room** when the child is waking up after the procedure is completed. Some facilities provide pullout beds for parents to spend the night with their children, and may even have a small kitchen where they can prepare food to eat in their child's room.

Qualified staff should be available to help parents work through their concerns and anxiety. Parents with more than one child may sometimes need to leave their hospitalized child completely in the hands of hospital staff as they attend to their other children at home. Many facilities have volunteers who can stay with children when their parents need to leave the hospital.

### *What to look for in health care for a child*

While those hospitals designed especially for children are a wonderful resource, other hospitals that care for patients of all ages will often provide comparable

care. If the surgery allows for time to select a surgeon and hospital, things to look for include:

- surgeons and physicians who are board certified in pediatrics
- staff with special training in pediatrics
- equipment designed for pediatric use
- a separate wing or floor for children
- child life specialists on staff
- play rooms and toys that can be brought into a child's room

A pediatric hospital or wing will have equipment that is smaller, better suited to the child's size. Bandages may have pictures of cartoon characters on them; there may be paintings of characters from children's movies on the walls.

Staff will usually have had special training to understand what issues are important to children at different stages of development. They should use language that is adapted to explain what is happening to the child in ways that make sense to them. For example, instead of just asking a child to blow, they may ask them to imagine that they are blowing out candles on a birthday cake. All of these techniques help to make the hospital a more familiar and friendlier place, putting the child at ease and helping to lessen anxiety.

## Pediatric surgery

### Definition

Pediatric surgery is a specialized field of surgery for the treatment of conditions that can be surgically corrected in a baby, child, or adolescent.

### Purpose

The purpose of pediatric surgery varies with the procedure. In general, the purpose is to surgically correct a congenital condition, disease, traumatic injury, or other disorder in the pediatric patient.

## Demographics

Pediatric surgeons provide treatment for young patients—newborns up through late adolescence.

## Description

Pediatric surgery is the surgical branch that uses operative techniques to correct certain pediatric conditions (i.e., congenital abnormalities, tumors, chronic diseases, and traumatic injuries). There are different specialties within the field that include:

- pediatric general surgery
- pediatric otolaryngology (ear, nose, and throat)
- pediatric ophthalmology (eye)
- pediatric urology (urogenital system)
- pediatric orthopedic (bone) surgery
- pediatric neurological (brain and spinal cord) surgery
- pediatric plastic (reconstructive and cosmetic) surgery

The American Academy of Pediatrics has established specific guidelines for referral to subspecialists. The pediatric patient has special considerations that differentiate him or her, both physically and psychologically, from an adult. A neonate (newborn) poses great challenge in surgical treatment since the tiny structures and immature organ systems may not cope with disease-induced stress and the physical demands of a major operative procedure. A newborn infant may still be developing key bodily functions, or may have special requirements. Key areas of concern in the newborn include:

- cardiovascular (heart) system
- thermoregulation (temperature requirements of 73°F [22.8°C]).
- pulmonary (lung) function
- renal (kidney) function
- immature immunity and liver
- special requirements for fluid, electrolyte (necessary elements such as sodium, potassium, and calcium) and nutrition

The pediatric surgeon must take into account the special requirements unique to the young surgical patient. The pediatric surgeon is trained to treat the entire spectrum of surgical illnesses. The following is an overview (with symptoms) of the more common pediatric conditions that require surgery typically performed by the pediatric surgeon.

## KEY TERMS

**Atresia**—Thinning or narrowing of a body passageway.

**Large intestine**—The portion of the colon that includes the cecum; ascending, transverse, and descending sigmoid colon; rectum; and anal canal.

**Oliguria**—Decreased urine production.

**Pediatric aged patient**—The pediatric aged patient encompasses several periods during development. The first four weeks after birth are called the neonatal period. The first year after birth is called infancy, and childhood is from 13 months until puberty (between the ages of 12 and 15 years in girls and 13 and 16 years in boys).

**Polyp**—A tumor mass, generally benign and capable of surgical removal.

**Pylorus**—The area that controls food passage from the stomach to the first part of the small intestine (duodenum).

**Small intestine**—The part of the intestines that consists of the duodenum, jejunum, and ileum.

### *Alimentary tract obstruction*

Obstruction of the alimentary tract (tubes of digestion extending from the mouth to the anus) is characterized by four cardinal symptoms:

- abdominal distention (an abdomen that becomes large and appears swollen)
- bilious vomiting (due to bile in the stomach)
- maternal polyhydramnios (excess amniotic fluid in the amniotic sac, greater than 2,000 ml) before birth
- failure to pass meconium (dark green or black sticky excretion passed via the newborn's rectum) in the first 24 hours of life

**ESOPHAGEAL ATRESIA AND TRACHEOESOPHAGEAL FISTULA.** This is a congenital deformity of the esophagus (the tube that passes food from the mouth to the stomach) does not connect to the stomach. Symptoms include severe respiratory distress (the neonate cannot breathe) and excessive salivation. Other clinical signs include cyanosis (bluish discoloration of the skin due to oxygen deprivation), choking, and coughing.

**PYLORIC ATRESIA AND RELATED CONDITIONS.** Pyloric atresia is a condition that occurs when the pyloric valve, located between the stomach and duodenum, fails to open. Food cannot pass out of the stomach, resulting in vomiting clear gastric juice at attempted

feedings. Maternal polyhydramnios is present before birth in more than 60% of cases.

Other areas of the colon (duodenum, jejunum, ileum) can be obstructed during development, with symptoms present at birth. Most of these disorders share the four cardinal symptoms of alimentary obstruction.

**INTUSSUSCEPTION.** Intussusception accounts for 50% of intestinal obstruction in patients who are three months to one year of age. Eighty percent of cases are observed by the child's second birthday. The cause of intussusception is not known, and it is more common in males who are well nourished and apparently healthy. The symptoms include a sudden onset of abdominal pain characterized by episodic screaming and drawing up of the legs. In 60% of patients, vomiting and blood in the stool are common findings (either bright red or occult [hidden] blood). Typically, the bowel movements look like currant jelly, consisting of mucus and blood mixed together. Currant jelly stool is the most common clinical observation for patients with intussusception. During **physical examination**, patients will exhibit abdominal distention, and in 65% of cases there is a sausage-shaped mass that can be felt in the upper right portion of the abdomen toward the mid-abdomen. **Ultrasound** studies are a reliable method of diagnosis.

**FAILURE TO PASS MECONIUM.** Failure to pass meconium (meconium ileus) is associated with cystic fibrosis (a genetic disorder), colonic obstruction (colonic atresia), meconium plug syndrome, and aganglionic megacolon (also called Hirschsprung's disease, a congenital absence of the nerves that provide gastrointestinal tract mobility).

### *Anorectal anomalies*

There are many different types of anorectal anomalies common to male and female neonates, as well as deformities that are gender-specific since involvement of genitalia can occur. The surgery for these cases is complicated, and must be performed by an experienced pediatric surgeon. Complications of these procedures could result in permanent problems.

### *Necrotizing enterocolitis (NEC)*

NEC affects 1–2% of patients admitted to a neonatal **intensive care unit**. It is a life-threatening illness characterized by abdominal distention, bilious vomiting, lethargy, fever, occult (not obvious) or gross (clearly seen) rectal bleeding. Additionally, affected patients may exhibit signs of hypothermia (temperature less than 96.5°F or 35.8°C), bradycardia (slow

heart rate), abdominal mass (felt during palpation), oliguria, jaundice, and episodes of breathlessness (apnea). Survival of NEC surgery can be expected for 60–70% of patients.

### *Abdominal wall defects*

Omphalocele is a defect that involves protrusion of abdominal contents into an external sac. This disorder occurs in one per 5,000 births. More than 50% of omphalocele patients have serious genetic deformities involving these body systems: cardiovascular (heart), musculoskeletal (muscle and bones), genitourinary (genital and bladder systems), and central nervous (brain and spinal cord). The overall survival rate for infants with omphalocele varies, and depends on defect size, other associated genetic abnormalities, and age of newborn. (Many infants with omphalocele are premature.) Approximately 33% of patients with omphaloceles do not survive.

**GASTROSCHISIS.** Gastroschisis is a defect in the abdominal wall to the side (lateral) of the umbilicus. It usually occurs to the right of an intact normal umbilical cord. The cause is unknown. The bowel protrudes to the outside of the abdomen during intra-uterine life (while the embryo is developing inside the uterus). The amniotic fluid has an irritating effect on the exposed bowel, and causes infection of the bowels. The problem can be detected by ultrasound studies during pregnancy. Some pediatric surgeons and obstetricians recommend **cesarean section** (early elective delivery) to spare bowel trauma. The newborn patients typically require surgery, tube feedings for three to four weeks, and hospitalization for several weeks. The current survival rate for infants with gastroschisis is greater than 90%.

### *Congenital diaphragmatic hernia (CDH)*

CDH can be diagnosed by the fourth month of pregnancy via ultrasound studies. Of the infants with congenital diaphragmatic hernia (CDH), 44–66% have other congenital abnormalities as a result of developmental malformations. Anatomically, patients with CDH have a defect in development that allows a communication between the chest and abdomen. Through this defect, the abdominal contents enter the lung cavity and interfere with normal lung development. The incidence is approximately one per 2,200 live births, and males are more commonly affected than females. Usually the infants are full-term, and the defect occurs on the left side in the majority—88%—of patients.

Treatment is extensive, and usually requires three major areas:

- stabilization of patient and preoperative preparation
- operative treatment
- postoperative respiratory, metabolic, circulatory and nutritional supportive measures

Postoperatively, the infant is monitored in the neonatal intensive care setting. The postoperative period is more critical if a lung is severely underdeveloped.

### *Pyloric stenosis (PS)*

Pyloric stenosis is an obstruction in the intestine due to a larger-than-normal size of the muscle fibers of the pylorus (lower stomach opening). Pyloric stenosis is a common hereditary condition that affects males more than females, and occurs in one per 750 births. The typical symptoms include a progressive, often projectile, vomiting after attempted feedings. The gastric vomitus (bloody in 80% of patients) usually begins during the second and third week of life, and increases in force and frequency. Typically, the infant fails to gain weight, and the number of bowel movements and rate of urination decreases.

Physical examination is usually helpful in establishing a diagnosis. Palpation of the enlarged muscle fibers can be felt as an olive-shaped mass located along the midline approximately one-third to one-half of the distance from the umbilicus to the xiphoid (end of the breastbone), when the stomach is empty. Careful abdominal examination and palpation can usually identify the pyloric mass in 85% of cases.

### *Gastroesophageal reflux*

Gastroesophageal reflux disease (GERD) is a common disorder in infancy, and usually disappears by the baby's first birthday. The largest group of patients with clinically significant GERD are those who have neurologic impairment. Symptoms often include vomiting, repeated lung infections (from aspirating gastric contents during regurgitation of food-stuffs), and delayed gastric emptying. The success rate with infants who have procedures necessary to correct GERD is over 90%.

### *Meckel's diverticulum*

Meckel's diverticulum occurs in approximately 2% of the U.S. population. The diverticulum is an outgrowth of intestine that is located in a portion of the intestines called the ileum. Symptoms of obstruction are more often observed in infants, and bleeding is more common in patients after age four.

### *Intestinal polyps*

Juvenile polyps are usually present between the ages of four and 14 years, and tend to be inflammatory. The most common symptom of intestinal polyps is rectal bleeding, which is commonly due to a solitary polyp (80% of cases). Diagnosis can be done by proctosigmoidoscopy, which allows visualization of 85% of polyps.

### *Acute appendicitis*

Acute appendicitis is a relatively common surgical emergency that is misdiagnosed in 28% of patients due to a broad spectrum of symptoms that can confuse the clinician. The classic clinical symptom of acute appendicitis is the onset of pain in the middle region of the abdomen that is followed by anorexia (loss of appetite), nausea, and vomiting. The pain is persistent and radiates to the right lower abdomen, becoming more intense and localized. The physical and abdominal examinations must be carefully and accurately performed. Patients with acute appendicitis usually have an increased white blood cell (cells that fight infection) count.

Once the diagnosis is established, the child is prepared for surgery. Preoperative **antibiotics** are started at least one half-hour before the operation. If the appendix is perforated (ruptured), complications can occur as a result of kidney (renal) failure, seizures due to fever, and gram-negative sepsis (an infection that enters the bloodstream and interferes with life-saving chemical reactions). Patients who are very young, or those who were misdiagnosed and incurred long delays in treatment, are susceptible to **death**.

### *Inflammatory bowel diseases*

Some cases (approximately 25%) of inflammatory bowel disease are found in persons younger than 20 years of age. Two types can occur, Crohn's disease and ulcerative colitis.

The diagnosis of inflammatory bowel disease is usually based on presenting clinical symptoms, laboratory analysis results, endoscopic appearance, and radiologic findings. Approximately 50–60% of patients have bloody diarrhea, severe cramping, abdominal pain, and urgency.

**CROHN'S DISEASE.** The symptoms of Crohn's disease includes cramping abdominal pain, diarrhea, and strictures (constriction) resulting from bowel obstruction. Removal of diseased portions in children with Crohn's disease may be temporarily beneficial, but recurrence after surgical removal occurs in about 50% of cases within four years. Chronic symptoms may

remain into adult life, making long-term follow-up essential.

**ULCERATIVE COLITIS.** Ulcerative colitis is limited to the colon. A surgical procedure known as colectomy is curative, and indicated for intractable disease (64% of patients). Colectomy is the removal of the entire colon, or the inflamed part of it.

### *Biliary tract disorders*

A variety of biliary tract conditions may be present at birth, some requiring surgical correction.

**NEONATAL JAUNDICE.** Neonatal jaundice is common, and results from an immature system not capable of some basic biochemical reactions. Food intake can help speed these reactions, which usually resolve the condition within seven to 10 days. Jaundice that persists for over two weeks is abnormal, and could be caused by over 30 possible disorders.

**BILIARY ATRESIA.** Biliary atresia is a disease that causes inflammation of the ducts within the biliary system, resulting in fibrosis of these ducts. The incidence of biliary atresia is one per 15,000 live births, and is more common in females. Time is critical, and most patients must have surgery by two months of life. Approximately 25–30% of patients who receive early operative intervention have long-term successful outcomes. Some patients may require **liver transplantation**, and 85–90% of these patients survive.

**CHOLELITHIASIS.** Gallbladder obstruction in infants and young children is usually caused by pigmented (colored) stones resulting from blood disorders. Removal of the gallbladder (laparoscopic **cholecystectomy**) is the treatment of choice.

### *Trauma*

Accidents are the leading cause of death in children between the ages of one and 15 years, and accounts for 50% of all deaths in the pediatric age group. More than half of these deaths are due to motor vehicle accidents, followed by falls, bicycle injuries, drowning, burns, child abuse, and birth trauma. Head trauma is the single most common organ associated with traumatic death. Within recent years, the number of fatalities related to the use of firearms and violence has increased.

More than 20 million children each year sustain injuries requiring treatment. These injuries account for 100,000 cases of permanent pediatric disability. Response to trauma in pediatric patients is significantly different from older patients. Pediatric patients require special attention concerning temperature regulation, blood volume, metabolic rate and requirements, and airway

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

Pediatric surgery is performed by a pediatric surgeon who has had five years of general surgery training, along with further specialized instruction and experience, and is certified in pediatric general surgery or in a specific pediatric specialty.

maintenance. Other special pediatric considerations include response to stress, communication difficulties, psychological trauma, a different pediatric trauma score system, smaller airway diameter, and increased risk of aspirating gastric contents (which could cause pneumonia). Pediatric trauma patients should have access to appropriate pre-hospital transportation, and must receive medical attention in a pediatric trauma center capable of providing the complex level of care necessary for serious pediatric trauma situations.

### *Neck masses*

Neck masses during infancy and childhood may be caused by tumors or infections, or they may be congenital. Lymphadenitis is an infection of a lymph node that becomes enlarged and tender. Most cases are resolved by treating the primary source of infection (i.e., middle ear infection and tonsillitis). Some inflamed nodes may require an incision and drainage of infection.

### *Hernias*

**INGUINAL HERNIA AND HYDROCELE.** Inguinal (groin) hernia is the most frequent disorder requiring surgery in the pediatric age group. Clinically, a right-sided inguinal hernia is more common in males (60% of cases), and there is a familial tendency. The incidence is higher in full-term infants (3.5–5%). Full-term infants and older children (without underlying diseases) can receive surgical repair in an outpatient setting. An inguinal hernia may result in herniation of the scrotum, and a communicating hydrocele (hernia with a small connection to the peritoneal cavity).

**UMBILICAL HERNIA.** Umbilical hernia is a defect of the umbilical ring, and is more common in females and African American children. Spontaneous involution occurs in 80% of cases. Larger defects may be observed for several years without complications, and their spontaneous resolution is possible. If the umbilical hernia persists, patients may develop feeding intolerance, pain, and local skin breakdown.

## QUESTIONS TO ASK THE DOCTOR

- What are the risks of surgery?
- What is the benefit of the surgery?
- What type of anesthesia will be used?
- How many surgeries of this type has the surgeon performed?
- Is there an alternative to surgery?
- Is a full recovery expected, and if not, what deficits will the child have?
- What should the parents and child do to prepare for surgery?
- What care is needed following the surgery?
- When will the child be able to return to normal activity?

### *Undescended testes*

Undescended testes are observed in 1–2% of full-term males. Approximately 30% of preterm males may have an undescended testis. Undescended testis in premature infants may descend by the first year of life, and observation is often the treatment during that time.

### *Tumors*

Wilm's tumor (nephroblastoma) is a tumor in the kidneys that forms during embryonic development. The tumor is due to a genetic abnormality; and approximately 80% of children are diagnosed between one and five years of age. In about 75–95% of cases, the patient has an abdominal mass that is detected by a parent during bathing. Blood in the urine (hematuria) occurs in 10–15% of cases, and high blood pressure (hypertension) is present in 20–25% of cases. Hypertension is the result of the tumor compressing the kidney in a specific area, causing it to release a chemical called renin, which elevates blood pressure. During physical examination, the Wilm's tumor is a smooth, round, hard, nontender flank mass. The treatment of Wilm's tumor depends on its stage, and may include surgery, chemotherapy, or radiotherapy.

# Pelvic ultrasound

## Definition

Pelvic **ultrasound** is a procedure in which high-frequency sound waves create images of the pelvic organs. The sound waves are projected into the pelvis, and measure how they reflect—or echo—back from the different tissues.

## Purpose

Ultrasound is a preferred method of examining the pelvis, and functions as an extension of a **physical examination**, particularly for obese patients. It is a common initial step after physical examination when a patient complains of pelvic pain or abnormal vaginal bleeding. The procedure is performed routinely during pregnancy and examinations to determine the cause of infertility. Ultrasound has the ability to detect the size and shape of pelvic organs, such as the bladder, and is useful in evaluating the cause of bladder dysfunction. In women, pelvic ultrasound is used to examine the uterus, ovaries, cervix, and vagina. In general, ultrasound can detect inflammation, free fluid, cysts (abnormal fluid-filled spaces), and tumors in the pelvic region.

A primary use of pelvic ultrasound is during pregnancy. In early pregnancy (about five to seven weeks), ultrasound may determine the size of the fetus to confirm the suspected due date, detect multiple fetuses, or confirm that the fetus is alive (viable). Ultrasound is particularly useful in distinguishing between intrauterine (within the uterus) and ectopic (outside the uterus) pregnancies. Toward the middle of the pregnancy (about 16–20 weeks), the procedure can confirm fetal growth, reveal defects in the anatomy of the fetus, and

check the placenta and amniotic fluid. Toward the end of pregnancy, it may be used to evaluate fetal size, position, growth, or to check the placenta.

Doctors may use ultrasound to guide the biopsy needle during **amniocentesis** and chorionic villus sampling. The imaging allows precise placement of the long needle that is inserted into the patient's uterus to collect cells from the placenta or amniotic fluid.

## Description

Depending on the goal of the procedure, a pelvic ultrasound can also be called a bladder ultrasound, pelvic gynecologic sonogram, or obstetric sonogram. Ultrasound examinations are usually done in a doctor's office, clinic, or hospital setting. Typically, the patient will lie on an examination table with the pelvis exposed. Special gel is applied to the area to make sure that there is no air between the hand-held transducer and the skin, and to facilitate transducer movement. The physician or technologist guides the transducer over the abdomen. The transducer both creates and receives the echoes of the high-frequency sound waves (usually in the range of 3.5–10.0 megahertz). An ultrasound scan reveals the shape and densities of organs and tissues. By performing repeated scans over time, much like the frames of a movie, ultrasound can also reveal movement, such as the motions of a fetus. This technique is called real-time ultrasound.

Using a computerized tool, called a caliper, the ultrasound technologist can measure various structures shown in the image. For example, the length of the upper thigh bone (femur) or the distance between the two sides of the skull can indicate the age of the fetus.

Ultrasound technology has been safely used in medical settings for over 30 years, and several significant extensions to the procedure have made it even more useful. A specially designed transducer probe can be placed in the vagina to provide better ultrasound images. This transvaginal or endovaginal scan is particularly useful in early pregnancy or in cases where ectopic pregnancy is suspected. It is also routinely used to provide better anatomic delineation of the endometrium and pelvic masses. In men, transrectal scans, where the probe is placed in the rectum, are done to check the prostate. Doppler ultrasound has the ability to follow the flow of blood through veins and arteries, and can be useful in detecting disorders such as abnormal blood flow associated with ovarian torsion (a twisted blood supply that causes pelvic pain). Color enhancement is particularly useful in Doppler imaging, where shades of red signify flow

## KEY TERMS

**Acoustic window**—Area through which ultrasound waves move freely.

**Amniocentesis**—A procedure where a needle is inserted through the pregnant woman's abdomen and into the uterus to withdraw a sample of amniotic fluid surrounding the fetus.

**Chorionic villus sampling**—A procedure where a needle is inserted into the placenta to withdraw a sample of the placenta's inner wall cells surrounding the fetus.

**Ectopic pregnancy**—A pregnancy where the fertilized egg becomes implanted somewhere other than in the uterus; if in a fallopian tube it is called a tubal pregnancy.

**Real-time**—A type of ultrasound that takes multiple images over time in order to record movement, or the observations obtained while scanning (rather than obtained by looking at films after the procedure).

**Sonographer**—A technologist or physician who uses an ultrasound unit to take ultrasound images of patients.

**Transducer**—The handheld part of the ultrasound unit that produces the ultrasound waves and receives the ultrasound echos.

**Ultrasound**—Sound above what can be heard by the human ear, generally above 20,000 Hz (cycles per second).

away from the transducer and shades of blue signify flow toward it.

Hysterosonography is another variant ultrasound procedure. It involves the injection of saline solution into the uterus during an endovaginal scan. The saline distends the uterine cavity (or endometrium) and simplifies the identification of polyps, fibroids, and tumors. The saline outlines the lesion, making it easier to find and evaluate. Hysterosonography can also be used in the testing of patency (openness) of the fallopian tubes during infertility evaluations.

### Preparation

Before undergoing a pelvic ultrasound, the patient may be asked to drink several glasses of water and to avoid urinating for about one hour prior to exam time. When the bladder is full, it forms a convenient path, called an acoustic window, for the ultrasonic waves. A full bladder is not necessary for an endovaginal

examination, sometimes making it a preferred choice in emergency situations. Women usually empty their bladders completely before an endovaginal exam.

### Aftercare

For a diagnostic ultrasound, the lubricating gel applied to the abdomen is wiped off at the end of the procedure and the patient can immediately resume normal activities.

### Risks

Ultrasound carries with it almost no risk for complications.

### Normal results

A normal scan reveals no abnormalities in the size, shape, or density of the organs scanned. During pregnancy, a normal scan reveals a viable fetus of expected size and developmental stage. Although ultrasound is an extremely useful tool, it cannot detect all problems in the pelvic region. If a tumor or other lesion is very small or if it is masked by another structure, it may not be detected. When used during pregnancy, patients should be advised that ultrasound does not reveal all fetal abnormalities. Additionally, the reliability of ultrasound readings can depend on the skill of the technologist or physician performing the scan.

An abnormal scan may show the presence of inflammation, cysts, tumors, or abnormal blood flow patterns. These results may suggest further diagnostic procedures, or surgical or pharmacological treatment. Obstetrical ultrasound examinations may alter the anticipated due date or detect abnormalities or defects in the fetus. This information may reveal that the fetus cannot survive on its own after birth, or that it will require extensive treatment or care. The technologist performing the ultrasound should consult with a radiologist or other physician if any questionable results appear.

Penile implant surgery see **Penile prostheses**

## Penile prostheses

### Definition

Penile prostheses are semi-rigid or inflatable devices that are implanted into penises to alleviate impotence.

### Purpose

The penis is composed of one channel for urine and semen, and three compartments with tough, fibrous walls containing erectile tissue. With appropriate stimulation, the blood vessels that lead out of these compartments constrict, trapping blood. Blood pressure fills and hardens the compartments producing an erection of sufficient firmness to perform sexual intercourse. Additional stimulation leads to ejaculation, where semen is pumped out of the urethra. When this system fails, erectile dysfunction or impotence (failure to create and maintain an erection) occurs.

Impotence can be caused by a number of conditions, including diabetes, spinal cord injury, prolonged drug abuse, and removal of the prostate gland. If the medical condition is irreversible, a penile prosthesis may be considered. Men whose impotence is caused by psychological problems are not recommended for implant surgery.

## KEY TERMS

**General anesthesia**—Deep sleep induced by a combination of medicines that allows surgery to be performed.

**Genital**—Sexual organ.

**Perineum**—Area between the anus and genitals.

**Scrotum**—The external pouch containing the male reproductive glands (testes) and part of the spermatic cord.

### Demographics

Recently, it has been reported that surgeons insert approximately 20,000 penile implants into American men yearly. The most common device is a multi-component inflatable implant (approximately 45% of all implants). Semi-rigid rods account for about 35% of the implants. Self-contained devices comprise approximately 20% of implants.

### Description

Penile implant surgery is conducted on persons who have exhausted all other areas of treatment. Semi-rigid devices consist of two rods that are easier and less expensive to implant than the inflatable cylinders. Once implanted, the semi-rigid device needs no follow-up adjustments; however, it produces a penis that constantly remains semi-erect. Inflatable cylinders produce a more natural effect. Men using them are able to simulate an erection via a pump located in the scrotum.

With a surgical patient under **general anesthesia**, the device is inserted into the erectile tissue of the penis through an incision in the fibrous wall. In order to insert the pump for the inflatable implant, incisions are made in the abdomen and the perineum (area between the anus and the genitals). A fluid reservoir is placed into the groin, and the pump is placed in the scrotum. The cylinders, reservoir, and pump are connected by tubes and tested before the incisions are closed.

### Diagnosis/Preparation

Surgery always requires a patient who is adequately informed about the procedure's risks and benefits. The sexual partner should also be involved in the discussion. Prior to surgery, the region undergoes antibacterial cleansing and is shaved.

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

A penile prosthesis is usually implanted by a urologist. This is a doctor with specialty training in diseases of the urinary system and the genital organs. The procedure is performed in a hospital with the patient under general anesthesia.

### Aftercare

To minimize swelling, ice packs are applied to the penis for the first 24 hours following surgery. The incision sites are cleansed daily to prevent infection. Pain relievers may be taken.

### Risks

With any implant, there is a slightly greater risk of infection than with simple surgery. The implant may irritate the penis and cause continuous pain. The inflatable prosthesis may need follow-up surgery to repair leaks in the reservoir or to reconnect the tubing.

### Normal results

Successful implantation of a penile prosthesis solves some problems related to impotence. After healing from the surgical procedure, men with a penile prosthesis can resume normal sexual activities.

### Morbidity and mortality rates

On a purely technical basis, morbidity associated with a surgically implanted penile implants is relatively uncommon, and is usually due to a postsurgical infection or to mechanical failure of the implanted device. Experts feel that personal dissatisfaction with a penile implant procedure is more common, and is usually due to unreasonable or inappropriate expectations for the procedure. Mortality is quite rare.

### Alternatives

Medication (sildenafil citrate [Viagra]) is useful for some men with erectile dysfunction. The medication must be prescribed and monitored by a physician.

Impotence caused psychological factors can usually be treated with appropriate counseling and therapy.

Creams are available for purchase. Most experts agree that these cannot reverse physiological impotence.

## QUESTIONS TO ASK THE DOCTOR

- What is the cause of the erectile dysfunction or impotence?
- How will the a penile prosthesis affect daily activities after recovery?
- How will the a penile prosthesis affect sexual activities after recovery?
- What will be the resulting appearance after surgery?
- Is the surgeon board certified?
- How many penile prosthesis procedures has the surgeon performed?
- What is the surgeon's complication rate?

Most experts consider mechanical rings that prevent blood flow out of a penis to be dangerous, and advise against their use.

## Pericardiocentesis

### Definition

A procedure performed with a needle to remove fluid for diagnostic or therapeutic purposes from the tissue covering the heart (pericardial sac).

### Purpose

The heart is surrounded by a membrane covering called the pericardial sac. The sac consists of two layers, the parietal (outer) and visceral (inner) layer, and normally contains a small amount of fluid to cushion and lubricate the heart as it contracts and expands. When too much fluid gathers in the pericardial cavity, the space between the pericardium and the outer layers of the heart, a condition known as pericardial effusion occurs. Abnormal amounts of fluid may result from:

- pericarditis, infection caused by inflammation of the pericardial sac
- trauma, such as an abnormal collection of blood due to an accident
- surgery or invasive heart procedures
- heart attack (myocardial infarction) or congestive heart failure, which occurs when the heart loses its pumping capability due to a heart condition
- kidney (renal) failure
- cancer (producing malignant effusions)

The rate of pericardial fluid accumulation is important. If fluid accumulation develops slowly, then problems with blood flow will not develop until fluid retention becomes massive. Blood can also enter the pericardial sac (hemopericardium) due to trauma, blood-thinning medications, or disease. When there is rapid or excessive build-up of fluid or blood in the pericardial cavity, the resulting compression on the heart impairs the pumping action of the vascular system (a condition called cardiac tamponade). Pericardiocentesis can be used in such an emergency situation to remove the excess accumulations of blood or fluid from the pericardial sac. For diagnostic purposes, pericardiocentesis may be advised in order to obtain fluid samples from the sac for laboratory analysis.

Prior to the discovery of **echocardiography**, pericardiocentesis was a risky procedure. The clinician had to insert a long needle below the breastbone into the pericardial sac without internal visualization. This blind approach was associated with damage to the lungs, coronary arteries, myocardium, and liver. However, with direct visualization using echocardiography, pericardiocentesis can now be performed with minor risk. Some risk is still associated with the procedure since it is considered an invasive measure.

### Demographics

Cardiac tamponade and pericarditis are two primary complications that require intervention with pericardiocentesis. Cardiac tamponade has an incidence of two in 10,000 the general U.S. population. Approximately 2% of cases are attributed to injuries that penetrate the chest. Pericarditis is more common in males than females, with a ratio of seven to three. In young adults, pericarditis is usually caused by HIV infection or a trauma injury. Malignancy or renal (kidney) failure are the main causes of this disorder in the elderly.

### Description

The patient should sit with the head elevated 30-40 degrees. This is done to maximize fluid drainage. A site close to the pericardial sac is chosen, and if time permits the patient is sedated. The puncture site is cleaned with an antiseptic iodine solution, and the area is shaved and anesthetized with lidocaine (a local anesthetic). A long cardiac needle is inserted under the xiphoid (the bottom of the breastbone) approach on the left side of the heart using guided imagery into the chest wall until the needle reaches the pericardial sac. Usually, the patient may experience a sensation of pressure when the tip of the needle penetrates the pericardial sac. When guided imagery confirms correct placement, fluid is aspirated from the sac.

## KEY TERMS

**Cardiac tamponade**—A condition caused by pericardial effusion, that seriously constrains cardiac contraction and access of blood to the heart.

**Echocardiography**—Sound waves that penetrate deep anatomical structures and generates a visual image on a monitor screen.

**Egobronchophony**—Increased intensity of the spoken voice.

**Hemodynamic**—Relating to the flow of blood through the circulatory system.

**Myocardial infarction**—A heart attack occurs when a coronary artery is blocked and blood flow to the blocked area is impaired.

**Parietal pericardium**—External or outer layer of the pericardial cavity.

**Pericardial friction rub**—A crackly, grating, low-pitched sound and is heard in both inspiration and expiration.

**Pulsus paradoxus**—A variation of the systolic pressure with respiration (diminished systolic pressure with inspiration and increased pressure with expiration).

**Tactile fremitus**—A tremor or vibration in any part of the body detected by palpation (palpation is when the clinician gently feels or presses with hands).

**Visceral pericardium**—Single layer of cells that lines both the internal surface of the heart with the parietal pericardium and the external surface of the heart.

If the procedure is performed for diagnostic purposes, aspirated fluid can be collected in specimen vials and sent for pathological analysis (i.e. for cancer cell detection in cases where malignant effusion is suspected), or the fluid is just removed if the procedure was performed urgently (i.e. cardiac tamponade). For therapeutic cases, a pericardial catheter may be attached and fixed into position to allow for continuous drainage. When the needle is removed, pressure is applied for five minutes at the puncture site to stop the bleeding, and the site is then bandaged.

### Diagnosis/Preparation

The typical symptom associated with patients requiring pericardiocentesis is chest pain, usually indicative of severe effusion. Patients with cardiac tamponade commonly have dyspnea (difficulty breathing)

and those with an infection may have fever. Some patients may have a hoarse voice from compression of a nerve called the recurrent laryngeal nerve; the pericardial sac may be so large that it pushes or compresses neighboring anatomical structures. Physical symptoms may vary, dependent both on size and the rate of filling of the pericardial effusion. Patients can also present with the following physical symptoms:

- tachycardia, an increased heart rate
- tachypnea, an increase in breathing rate
- jugular vein enlargement
- narrow pulse pressure (pulsus paradoxus)
- pericardial friction rub
- elevated central venous pressure
- hiccups from esophageal compression
- Ewart's sign (dull sound when the doctor taps the chest, tactile fremitus, egobronchophony)

The procedure can be performed in an emergency room, ICU, or at the bedside. Before the procedure patients should have an echocardiogram and basic blood analysis. No special dietary restrictions are required for pericardiocentesis. The patient will receive an IV line for sedation or other necessary medications and an **electrocardiogram** (ECG) to monitor cardiac activity. The patient must lie flat on the table, with the body elevated to a 60-degree angle. If the test is elective, then food and water restriction is recommended for six hours before the test. For infants and children, preparation depends on the child's age, level of trust, and previous exposure to this or similar procedures.

### Aftercare

The puncture site, or if a catheter is fixed in place, the catheter site, should be inspected regularly for signs of infection such as redness or swelling. **Vital signs** such as blood pressure and pulse are monitored following the procedure.

### Risks

Pericardiocentesis is an invasive procedure and therefore has associated risks. Complications are possible, but have become less common due to guided imaging techniques that improved the past blind approach. Possible risks include:

- puncture of the myocardium, the outer muscle layer of the heart
- puncture of a coronary artery, a blood vessel that supplies blood to heart muscle
- myocardial infarction (heart attack)

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

A cardiologist who has received three years of training in internal medicine and three years of cardiology training typically performs the procedure. A general surgeon can also perform pericardiocentesis and typically have five years of surgical training. The procedure is performed in a hospital, either in the ER (emergency room), ICU (intensive care unit), or bedside.

- needle induced arrhythmias (irregular heartbeats)
- pneumopericardium, air entry into the pericardial sac
- infection of the pericardial membranes (pericarditis)
- accidental puncture of the stomach, lung, or liver

### Normal results

Normal pericardial fluid is clear to straw colored. During pathological examination normal pericardial fluid does not contain blood, cancer cells, or bacteria. In most individuals, a small amount of fluid (10–50 ml) is in the pericardial sac to cushion the heart. Pericardial fluid volumes over 50 ml suggest pericardial effusion. The presence of microorganisms (such as *Staphylococcus aureus*) in aspirated pericardial fluid indicates bacterial pericarditis. Blood in pericardial fluid can be seen in patients with cancer; cardiac rupture, which can occur with myocardial infarction (heart attack); or hemorrhage due to traumatic injury or accident.

### Morbidity and mortality rates

The success of pericardiocentesis has greatly improved with the use of guided imagery during the procedure. Only about 5% of patients will experience a major complication as a result of pericardiocentesis. Cardiac tamponade is fatal in almost all cases unless the excess fluid in the pulmonary sac is removed.

## Peripheral endarterectomy

### Definition

A peripheral endarterectomy is the surgical removal of fatty deposits, called plaque, from the walls of arteries other than those of the heart and brain. The surgery is performed when plaque blocks an artery and obstructs the flow of blood and oxygen to other parts of the body, most commonly the legs but also the arms, kidneys, or intestines. The peripheral arteries most often treated with endarterectomy are those that supply the legs, especially the aortoiliac arteries in the pelvic area. Other arteries that may be treated with endarterectomy include the femoral arteries in the groin, the renal arteries that supply the kidneys, and the superior mesenteric arteries that supply the intestines.

### Purpose

Endarterectomy surgeries are performed to treat advanced peripheral arterial disease (PAD). PAD

most often occurs as a result of atherosclerosis, a condition characterized by the gradual build up of fats, cholesterol, cellular waste, calcium, and other substances on the inner walls of large and medium-sized arteries. Plaque, the hardened, waxy substance that results from this build up, can cause narrowing (stenosis) of an artery and block the flow of blood and oxygen. Peripheral endarterectomies are performed to reopen blocked arteries and to restore blood flow in the body (revascularization), helping to prevent heart attack, stroke, the **amputation** of a limb, organ failure, or **death**.

### Demographics

People who have been diagnosed with PAD caused by atherosclerosis are at high risk of arterial blockage (occlusion) and are candidates for peripheral endarterectomy. Occlusive arterial disease is found in 15 to 20% of men and women older than age 70. When found in people younger than 70, it occurs more often in men than in women, particularly in those who have ever smoked or who have diabetes. Women with PAD live longer than men with the same condition, which accounts for the equal incidence in older Americans. African-Americans have been shown to be at greater risk for arterial occlusion than other racial groups in the United States.

### Description

PAD is a progressive occlusive disease of the arteries, common in older people who have ever smoked or who have diabetes. Although there are other forms of arterial disease that affect peripheral arteries (Buerger's disease, Raynaud's disease, and acrocyanosis), PAD in most people is caused by widespread atherosclerosis, the accumulation of plaque on the inner lining (endothelium) of the artery walls. Most commonly, occlusive PAD develops in the legs, including the femoral arteries that supply the thighs with blood or in the common iliac arteries, which are branches of the lower abdominal aorta that also supply the legs. The arteries that supply the shoulders and arms are less commonly affected. Branches of the aorta that deliver blood to the kidneys, the infrarenal aorta and renal arteries, can become narrowed as a result of atherosclerosis, but are only rarely blocked suddenly and completely, a condition requiring immediate surgery. Even more rare is blockage of the branches that supply the liver and spleen.

The development of atherosclerosis and PAD is influenced by heredity and also by lifestyle factors,

## KEY TERMS

**Atheroma**—A collection of plaque (lesion) blocking a portion of an artery.

**Atherosclerosis (arteriosclerosis)**—A process of thickening and hardening of large and medium-sized arteries as a result of fatty deposits on their inner linings.

**Ischemia**—An inadequate blood supply (circulation) in an area of the body when arteries in the area are blocked.

**Peripheral arterial disease (PAD)**—An occlusive disease of the arteries most often caused by progressive atherosclerosis.

**Peripheral endarterectomy**—The surgical removal of fatty deposits, called plaque, from the walls of arteries other than those of the heart and brain.

**Plaque**—A collection of wax-like fatty deposits on the insides of artery walls.

**Restenosis**—The repeat narrowing of blood vessels that may occur after surgical removal of plaque when preventive measures are not taken.

**Revascularization**—Restoring normal blood flow (circulation) in the body's vascular (veins and arteries) system.

**Stenosis**—The narrowing of a blood vessel.

such as dietary habits and levels of **exercise**. The risk factors for atherosclerosis include:

- high levels of blood cholesterol and triglycerides
- high blood pressure
- cigarette smoking or exposure to tobacco smoke
- diabetes, types I and II
- obesity
- inactivity, lack of exercise
- family history of early cardiovascular disease

Just as coronary artery disease (CAD) can cause a heart attack when plaque blocks the arteries of the heart, or blockage in the carotid artery leading to the brain can cause a stroke, blockage of the peripheral arteries can create life-threatening conditions. When peripheral arteries have become narrowed by plaque accumulation (atheroma), the flow of oxygen-carrying blood to the arms, legs, or body organs will be interrupted, which can cause cell death from lack of oxygen (ischemia) and nutrition. Normal growth and cell repair cannot take place, which can lead to gangrene in the limbs and subsequent amputation. When blood

flow is blocked to internal organs, such as the kidneys or intestines, the result of tissue death can be the shut-down of the affected organ system and systemic (whole body) poisoning from waste accumulation. Death can result if **emergency surgery** is not performed to correct the blockage.

In some cases, the body will attempt to change the flow of blood when a portion of an artery is blocked by plaque. Smaller arteries around the blockage will begin to take some of the blood flow. This adaptation of the body (collateral circulation) is one reason for a lack of symptoms in some people who actually have PAD. Symptoms usually occur when the blockage is over 70% or when complete blockage occurs as a result of a piece of plaque breaking off and blocking the artery. Blockage in the legs, for example, will reduce or cut off circulation, causing painful cramping in the legs during walking (intermittent claudication) and pain in the feet during rest, especially during the night. When an artery gradually becomes narrowed by plaque, the symptoms are not as severe as when sudden, complete blockage occurs. Sudden blockage does not offer time for collateral vessels to develop and symptoms can be equally sudden and dramatic. Possible symptoms of reduced blood flow in the most typically affected arteries include:

- Arteries of the arms and legs: Gradual blockage creates muscle aches and pain, cramping, and sensations of tiredness or numbness; sudden blockage may cause severe pain, coldness and numbness. A leg or arm may become blue (cyanotic) from lack of oxygen. No pulse will be felt. Paralysis may occur.
- Lower aorta, femoral artery, and common iliac arteries: Gradual narrowing causes intermittent claudication affecting the buttocks and thighs. Men may become impotent. Sudden blockage will cause both legs to become painful, pale, and cold. No pulse will be felt. Legs may become numb. The feet may become painful, infected, or even gangrenous when gradual or complete blockage limits or cuts off circulation
- Renal arteries: Gradual narrowing may produce no symptoms and no change in kidney function. Sudden, complete blockage may cause sudden pain in the side and bloody urine. This is an emergency situation.
- Superior mesenteric artery: Gradual narrowing causes steady, severe pain in the middle of the abdomen about 30 to 60 minutes after a meal. Nutrients are lost and weight loss is common. Sudden, complete blockage causes severe abdominal pain, vomiting, and the urge to move the bowels. Blood pressure falls, intestinal gangrene may develop, and the patient may go into shock. This is an emergency situation.

Sudden, complete occlusion of an artery can also happen when a clot (thrombus) forms in an already narrowed artery. Clot formation (thrombosis) can occur anywhere in the body and travel to a narrowed portion of an affected artery and become lodged (embolism), blocking blood flow. Clots can sometimes be dissolved with anticoagulant drug therapy. When this therapy is not effective or a life-threatening blockage occurs suddenly, clots can be surgically removed using thromboendarterectomy, a procedure similar to peripheral endarterectomy.

Early treatment for PAD may include medical treatment to reduce the underlying causes: lowering cholesterol, lowering blood pressure, stopping smoking, increasing exercise, and reducing the likelihood of clot formation. Clot-dissolving drugs (thrombolytic drugs) may also be used to remove a clot medically rather than to perform surgery. When these measures are not effective, or an artery becomes completely blocked, peripheral endarterectomy may be performed to remove the blockage (see also **angioplasty** and **peripheral vascular bypass surgery**). Treatment of risk factors must continue, because surgery only corrects the immediate problem, not the underlying causes.

Peripheral endarterectomy works best in narrow areas like the leg where the artery can be easily accessed, or when there is complete blockage of an artery by an atheroma that is short in length. Endarterectomy does not work as well for smaller arteries lower in the leg or in the foot or arm. Drug therapy, **angiography**, stent placement, or surgical bypass may be used to treat blockages of the arteries in these areas.

Patients undergoing peripheral endarterectomy will typically be given **general anesthesia**. The surgery is an open surgical procedure in which a vascular surgeon makes a relatively large incision in the outer skin to access the obstructed artery being treated. In order to perform the surgery, the blood that normally flows through the artery must first be rerouted through a tube connecting the blood vessels below and above the surgical site. The surgeon will then cut the obstructed artery lengthwise and will use surgical tools to clean away the accumulation of plaque. The hard, waxy substance comes out fairly easily, sometimes in a single piece. The artery will then be sutured closed or patched with a piece of a vein, usually from the patient's leg, to enlarge the repaired artery and prevent later narrowing from post-operative scarring. The entire procedure will take about one hour if there are no complications.

## Diagnosis/Preparation

A complete patient history is essential to diagnosis, particularly information about family members who may have had diabetes or early cardiovascular disease. Symptoms will be important diagnostic indicators, letting the physician know what areas of the body may have reduced blood flow. Blood pressure will be taken in the arms and legs. Pulses will be measured in the arms, armpits, wrists, groin, ankles, and behind the knees. This will show where blockages may exist, since the pulse below a blockage is usually absent. Additionally, a **stethoscope** will be used to listen for abnormal sounds in the arteries that may indicate narrowing. Blood flow procedures may be performed, including:

- Doppler ultrasonography—direct measurement of blood flow and rates of flow, sometimes performed in conjunction with stress testing (exercise between tests).
- Angiography—an x-ray procedure that provides clear images of the affected arteries before surgery is performed.
- Blood tests—routine tests such as cholesterol and glucose, as well as tests to help identify other causes of narrowed arteries, such as inflammation, thoracic outlet syndrome, high homocysteine levels, or arteritis.
- Spiral computed tomography (CT angiography) or magnetic resonance angiography (MRI)—less invasive forms of angiography.

If ultrasonography or angiography procedures were not performed earlier to diagnose arterial blockage, these tests will be performed before surgery to evaluate the amount of plaque and the extent and exact location of narrowing. **Aspirin** therapy or other clot-prevention medication may be prescribed before surgery. Any underlying medical condition, such as high blood pressure, heart disease, or diabetes will be treated prior to peripheral endarterectomy to help get the best result from the surgery. Upon **admission to the hospital**, routine blood and urine tests will be performed.

## Aftercare

After the peripheral endarterectomy, the patient's blood pressure, temperature, and heart rate will be monitored in a hospital **recovery room** for an hour or more, and the surgical site will be checked regularly. The patient will then be transferred to a concentrated care unit to be observed for any sign of complications. The total hospital stay may be two to three days. When

the patient returns home, activities can be resumed gradually. Walking and strenuous activity may be restricted, especially if surgery was performed on the groin or leg. During recuperation, the patient may be given pain medication as needed and clot prevention (anticoagulant) medication. Patients will be advised to reduce the risk factors for atherosclerosis in order to avoid repeat narrowing or blockage of the arteries. Repeat stenosis (restenosis) has been shown to occur frequently in people who do not make the necessary changes in lifestyle, such as changes in diet, exercise, and quitting smoking. The benefits of the surgery may only be temporary if underlying disease, such as atherosclerosis, high blood pressure, or diabetes, is not also treated.

## Risks

The risks associated with peripheral endarterectomy primarily involve the underlying conditions that led to blockage of arteries in the first place. Embolism is the most serious postoperative risk; a clot or piece of tissue from the endarterectomy site that may travel to the heart, brain, or lungs can cause heart attack, stroke, or death. Restenosis, the continuing build-up of plaque, can occur within months to years after surgery if risk factors are not controlled. Other complications may include:

- reactions to anesthesia
- breathing difficulties
- changes in blood pressure
- nerve injury
- postoperative bleeding

## Normal results

The outcomes of peripheral endarterectomy as a treatment for arterial blockage are usually good. Blood flow can be restored quickly to relieve symptoms and help prevent heart attack, stroke, organ failure, or limb amputation.

## Morbidity and mortality rates

Morbidity and mortality depend upon the artery involved, the extent of the blockage, and the patient's overall condition, which directly influences response to the surgery. Time is also a factor. In cases of sudden and complete blockage of the mesenteric arteries, for example, only immediate surgery can save the person's life. Although death does not frequently occur during peripheral endarterectomy surgery, patients with widespread atherosclerosis and PAD have been shown to have increased morbidity and mortality associated with

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

Peripheral endarterectomy is performed in a hospital operating room by a vascular surgeon.

coronary artery disease, because of the common risk factors, such as cigarette smoking, high blood pressure, and diabetes. PAD patients with diabetes are shown to represent 50% of all amputations. However, only a small percentage of patients undergoing peripheral endarterectomy will suffer limb loss or associated disability and reduced quality of life.

### Alternatives

Peripheral endarterectomy removes plaque directly from blocked arteries; there is no alternative way to mechanically remove plaque. However, there are alternative ways to prevent plaque build-up and reduce the risk of narrowing or blocking the peripheral arteries. Certain vitamin deficiencies in older people, for example, are known to promote high levels of homocysteine, an amino acid that contributes to atherosclerosis and a higher risk for PAD. Some nutritional supplements and alternative therapies that are recommended to help promote good vascular health include:

- Folic acid can help lower homocysteine levels and increase the oxygen-carrying capacity of red blood cells.
- Vitamins B<sub>6</sub> and B<sub>12</sub> help lower homocysteine levels.
- Antioxidant vitamins C and E work together to promote healthy blood vessels and improve circulation.
- Angelica, an herb that contains Coumadin, a recognized anticoagulant, may help prevent clot formation in the blood.
- Essential fatty acids, as found in flax seed and other oils, can help reduce blood pressure and cholesterol, and maintain elasticity of blood vessels.
- Chelation therapy may be used to break up plaque and improve circulation.

## QUESTIONS TO ASK THE DOCTOR

- Why do I need this surgery?
- How will the surgery improve my condition?
- What kind of anesthesia will I be given?
- What are the risks of having this surgery?
- How many of these procedures have you performed? How many of the surgery patients had complications after surgery?
- How can I expect to feel after surgery? How long will it take me to recover?
- What are my chances of developing this problem again after the surgery?
- What can I do to help prevent developing this condition again?

## Peripheral vascular bypass surgery

### Definition

A peripheral vascular bypass, also called a lower extremity bypass, is the surgical rerouting of blood flow around an obstructed artery that supplies blood to the legs and feet. This surgery is performed when the build-up of fatty deposits (plaque) in an artery has

blocked the normal flow of blood that carries oxygen and nutrients to the lower extremities. Bypass surgery reroutes blood from above the obstructed portion of an artery to another vessel below the obstruction.

A bypass surgery is named for the artery that will be bypassed and the arteries that will receive the rerouted blood. The three common peripheral vascular bypass surgeries are:

- Aortobifemoral bypass surgery, which reroutes blood from the abdominal aorta to the two femoral arteries in the groin.
- Femoropopliteal bypass (fem-pop bypass) surgery, which reroutes blood from the femoral artery to the popliteal arteries above or below the knee.
- Femorotibial bypass surgery, which reroutes blood between the femoral artery and the tibial artery.

A substitute vessel or graft must be used in bypass surgeries to reroute the blood. The graft may be a healthy segment of the patient's own saphenous vein (autogenous graft), a vein that runs the entire length of the thigh. A synthetic graft may be used if the patient's saphenous vein is not healthy or long enough, or if the vessel to be bypassed is a larger artery that cannot be replaced by a smaller vein.

### Purpose

Peripheral vascular bypass surgery is performed to restore blood flow (revascularization) in the veins and arteries of people who have peripheral arterial disease (PAD), a form of peripheral vascular disease (PVD). People with PAD develop widespread hardening and narrowing of the arteries (atherosclerosis) from the gradual build-up of plaque. In advanced PAD, plaque accumulations (atheromas) obstruct arteries in the lower abdomen, groin, and legs, blocking the flow of blood, oxygen, and nutrients to the lower extremities (legs and feet). Rerouting blood flow around the blockage is one way to restore circulation. It relieves symptoms in the legs and feet, and helps avoid serious consequences such as heart attack, stroke, limb **amputation**, or **death**.

### Demographics

Approximately 8–8 million people in the United States have PAD caused by atherosclerosis. These people are at high risk of arterial occlusion, and are candidates for peripheral vascular bypass surgery. Occlusive arterial disease is found in 12–20% of men and women older than age 65. In people younger than age 70, it occurs more often in men than women, particularly in those who have ever smoked or who

## KEY TERMS

**Atheroma**—An accumulation of plaque blocking a portion of an artery.

**Atherosclerosis (arteriosclerosis)**—Process of thickening and hardening of large- and medium-sized arteries as a result of fatty deposits on their inner linings.

**Intermittent claudication**—Pain that occurs on walking and is relieved on rest.

**Ischemia**—An inadequate blood supply (circulation) in a part of the body where arteries are blocked.

**Peripheral arterial disease (PAD)**—An occlusive disease of the arteries most often caused by progressive atherosclerosis.

**Peripheral arteries**—Arteries other than those of the heart and brain, especially those that supply the lower body organs and limbs.

**Plaque**—A collection of wax-like fatty deposits on the insides of artery walls.

**Restenosis**—The repeat narrowing of blood vessels that may occur after surgical removal of plaque when preventive measures are not taken.

**Revascularization**—Restoring normal blood flow (circulation) in the body's vascular (veins and arteries) system.

**Stenosis**—Narrowing of a blood vessel.

have diabetes. Women with PAD live longer than men with the same condition, accounting for the equal incidence in older Americans. African-Americans are at greater risk for arterial occlusion than other racial groups in the United States.

### Description

The circulatory system delivers blood, oxygen, and vital nutrients to the limbs, organs, and tissues throughout the body. This is accomplished via arteries that deliver oxygen-rich blood from the heart to the tissues and veins that return oxygen-poor blood from organs and tissues back to the heart and lungs for re-oxygenation. In PAD, the gradual accumulation of plaque in the inner lining (endothelium) of the artery walls results in widespread atherosclerosis that can occlude the arteries and reduce or cut off the supply of blood, oxygen, and nutrients to organ systems or limbs.

Peripheral vascular bypass surgery is a treatment option when PAD affects the legs and feet. PAD is similar to coronary artery disease (CAD), which leads to heart attacks and carotid artery disease (CAD), which causes stroke. Atherosclerosis causes each of these diseases. Most often, atherosclerotic blockage or narrowing (stenosis) occurs in the femoral arteries that supply the thighs with blood or in the common iliac arteries, which are branches of the lower abdominal aorta that also supplies the legs. The popliteal arteries (a portion of the femoral arteries near the surface of the legs) or the posterior tibial and peroneal arteries below the knee (portions of the popliteal artery) can be affected.

Just as coronary artery disease can cause a heart attack when plaque blocks the arteries of the heart, or blockage in the carotid artery leading to the brain can cause a stroke, occlusion of the peripheral arteries can create life-threatening conditions. Plaque accumulation in the peripheral arteries blocks the flow of oxygen-carrying blood, causing cells and tissue in the legs and feet to die from lack of oxygen (ischemia) and nutrition. Normal growth and cell repair cannot take place, which can lead to gangrene in the limbs and subsequent amputation. If pieces of the plaque break off, they can travel from the legs to the heart or brain, causing heart attack, stroke, or death.

The development of atherosclerosis and PAD is influenced by heredity and also by lifestyle factors, such as dietary habits and levels of **exercise**. The risk factors for atherosclerosis include:

- high levels of blood cholesterol and triglycerides.
- high blood pressure (hypertension)
- cigarette smoking or exposure to tobacco smoke
- diabetes, types 1 and 2
- obesity
- inactivity, lack of exercise
- family history of early cardiovascular disease

Sometimes the body will attempt to change the flow of blood when a portion of an artery is narrowed by plaque. Smaller arteries around the blockage begin to take over some of the blood flow. This adaptation of the body (collateral circulation) is one reason for the absence of symptoms in some people who have PAD. Another reason is that plaque develops gradually as people age. Symptoms usually don't occur until a blockage is over 70%, or when a piece of plaque breaks off and blocks an artery completely. Blockage in the legs reduces or cuts off circulation, causing painful cramping during walking, which is relieved

on rest (intermittent claudication). The feet may ache even when lying down at night.

When narrowing of an artery occurs gradually, symptoms are not as severe as they are when sudden, complete blockage occurs. Sudden blockage does not allow time for collateral vessels to develop, and symptoms can be severe. Gradual blockage creates muscle aches and pain, cramping, and sensations of fatigue or numbness in the limbs; sudden blockage may cause severe pain, coldness, and numbness. At times, no pulse can be felt, a leg may become blue (cyanotic) from lack of oxygen, or paralysis may occur.

When the lower aorta, femoral artery, and common iliac arteries (all in the lower abdominal and groin areas) are blocked, gradual narrowing may produce cramping pain and numbness in the buttocks and thighs, and men may become impotent. Sudden blockage will cause both legs to become painful, pale, cold, and numb, with no pulse. The feet may become painful, infected, or even gangrenous when gradual or complete blockage limits or cuts off circulation. Feet may become purple or red, a condition called rubor that indicates severe narrowing. Pain in the feet or legs during rest is viewed as an indication for bypass surgery because circulation is reduced to a degree that threatens survival of the limb.

Early treatment for PAD usually includes medical intervention to reduce the causes of atherosclerosis, such as lowering cholesterol and blood pressure, **smoking cessation**, and reducing the likelihood of clot formation. When these measures are not effective, or an artery becomes completely blocked, lower extremity bypass surgery may be performed to restore circulation, reduce foot and leg symptoms, and prevent limb amputation.

Bypass surgery is an open procedure that requires **general anesthesia**. In femoropopliteal bypass or femorotibial bypass, the surgeon makes an incision in the groin and thigh to expose the affected artery above the blockage, and another incision (behind the knee for the popliteal artery, for example) to expose the artery below the blockage. The arteries are blocked off with vascular clamps. If an autogenous graft is used, the surgeon passes a dissected (cut and removed) segment of the saphenous vein along the artery that is being bypassed. If the saphenous vein is not long enough or is not of good quality, a tubular graft of synthetic (prosthetic) material is used. The surgeon sutures the graft into an opening in the side of one artery and then into the side of the other. In a femoropopliteal bypass, for example, the graft extends from the femoral artery to the popliteal artery. The clamps are then removed

and the flow of blood is observed to make sure it bypasses the blocked portion of the affected artery.

Aortobifemoral bypass surgery is conducted in much the same way, although it requires an abdominal incision to access the lower portion of the abdominal aorta and both femoral arteries in the groin. This is generally a longer and more difficult procedure. Synthetic grafts are used because the lower abdominal aorta is a large conduit, and its blood flow cannot be handled by the smaller saphenous vein. Vascular surgeons prefer the saphenous vein graft for femoropopliteal or femorotibial bypass surgery because it has proven to stay open and provide better performance for a longer period of time than synthetic grafts. Bypass surgery patients will be given heparin, a blood thinner, immediately after the surgery to prevent clotting in the new bypass graft.

## Diagnosis/Preparation

### Diagnosis

After obtaining a detailed history and reviewing symptoms, the physician examines the legs and feet, and orders appropriate tests or procedures to evaluate the vascular system. Diagnostic tests and procedures may include:

- Blood pressure and pulses—pressure measurements are taken in the arms and legs. Pulses are measured in the arms, armpits, wrists, groin, ankles, and behind the knees to determine where blockages may exist, since no pulse is usually felt below a blockage.
- Doppler ultrasonography—direct measurement of blood flow and rates of flow, sometimes performed in conjunction with stress testing (tests that incorporate an exercise component).
- Angiography—an x-ray procedure that provides clear images of the affected arteries before surgery is performed.
- Blood tests—routine tests such as cholesterol and glucose, as well as tests to help identify other causes of narrowed arteries, such as inflammation, thoracic outlet syndrome, high homocysteine levels, or arteritis.
- Spiral computed tomography (CT angiography) or magnetic resonance angiography (MRA)—less invasive forms of angiography.

### Preparation

If not done earlier in the diagnostic process, ultrasonography or **angiography** procedures may be performed when the patient is admitted to the hospital. These tests help the physician evaluate the amount of

plaque and exact location of the narrowing or obstruction. Any underlying medical condition, such as high blood pressure, heart disease, or diabetes is treated prior to bypass surgery to help obtain the best surgical result. Regular medications, such as blood pressure drugs or **diuretics**, may be discontinued in some patients. Routine pre-operative blood and urine tests are performed when the patient is admitted to the hospital.

## Aftercare

After bypass surgery, the patient is moved to a recovery area where blood pressure, temperature, and heart rate are monitored for an hour or more. The surgical site is checked regularly. The patient is then transferred to a concentrated care unit to be observed for any signs of complications. The total hospital stay for femoropopliteal bypass or femorotibial bypass surgery may be two to four days. Recovery is slower with aortobifemoral bypass surgery, which involves abdominal incisions, and the hospital stay may extend up to a week. Walking will begin immediately for patients who have had femoropopliteal or femorotibial bypasses, but patients who have had aortobifemoral bypass may be kept in bed for 48 hours. When bypass patients go home, walking more each day, as tolerated, is encouraged to help maintain blood flow and muscle strength. Feet and legs can be elevated on a footstool or pillow when the patient rests. Some swelling of the leg should be expected; it does not indicate a problem and will resolve within a month or two.

During recuperation, the patient may be given pain medication if needed, and clot prevention (anti-coagulant) medication. Any redness of the surgical site or other signs of infection will be treated with **antibiotics**. Patients are advised to reduce the risk factors for atherosclerosis in order to avoid repeat narrowing or blockage of the arteries. Repeat stenosis (restenosis) has been shown to occur frequently in people who do not make the necessary lifestyle modifications, such as changes in diet, exercise, and smoking cessation. The benefits of the bypass surgery may only be temporary if underlying disease, such as atherosclerosis, high blood pressure, or diabetes, is not also treated.

## Risks

The risks associated with peripheral vascular bypass surgery are related to the progressive atherosclerosis that led to arterial occlusion, including a return of pre-operative symptoms. In patients with advanced PAD, heart attack or heart failure may occur. Build up of plaque has also taken place in the

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

Peripheral vascular bypass surgery is performed by a vascular surgeon in a hospital operating room.

patient's arteries of the heart. Restenosis, the continuing build up of plaque, can occur within months to years after surgery if risk factors are not controlled. Other complications may include:

- clot formation in a saphenous vein graft
- failed grafts or blockages in grafts
- reactions to anesthesia
- breathing difficulties
- embolism (clot from the surgical site traveling to vessels in the heart, lungs, or brain)
- changes in blood pressure
- infection of the surgical wound
- nerve injury (including sexual function impairment after aortobifemoral bypass)
- postoperative bleeding
- failure to heal properly

### Normal results

A femoropopliteal or femorotibial bypass with an autogenous graft of good quality saphenous vein has been shown to have a 60–70% chance of staying open and functioning well for five to 10 years. Aortobifemoral bypass grafts have been shown to stay open and reduce symptoms in 80% of patients for up to 10 years. Pain and walking difficulties should be relieved after bypass surgery. Success rates improve when the underlying causes of atherosclerosis are monitored and managed effectively.

### Morbidity and mortality rates

The risk of death or heart attack is about 3–5% in all patients undergoing peripheral vascular bypass surgery. Following bypass surgery, amputation is still an outcome in about 40% of all surgeries performed, usually due to progressive atherosclerosis or complications caused by the patient's underlying disease condition.

## QUESTIONS TO ASK THE DOCTOR

- Why is this surgery necessary?
- How will the surgery improve my condition?
- What kind of anesthesia will be given?
- How many of these procedures has the surgeon performed?
- How many surgical patients had complications after the procedure?
- How can the patient expect to feel after surgery?
- How soon will the patient be able to walk?
- How long will it take to recover completely?
- What are the chances of this problem recurring after surgery?
- What can be done to help prevent this problem from developing again?

### Alternatives

Peripheral vascular bypass surgery is a mechanical way to reroute blood, and there is no alternative method. Alternative ways to prevent plaque build-up and reduce the risk of narrowing or blocking the peripheral arteries include nutritional supplements and alternative therapies, such as:

- Folic acid can help lower homocysteine levels and increase the oxygen-carrying capacity of red blood cells.
- Vitamins B<sub>6</sub> and B<sub>12</sub> help lower homocysteine levels.
- Antioxidant vitamins C and E work together to promote healthy blood vessels and improve circulation.
- Angelica, an herb that contains Coumadin, a recognized anticoagulant, which may help prevent clot formation in the blood.
- Essential fatty acids, as found in flax seed and other oils, to help reduce blood pressure and cholesterol, and maintain blood vessel elasticity.
- Chelation therapy, used to break up plaque and improve circulation.

Peritoneal dialysis see **Kidney dialysis**

Peritoneal fluid analysis see **Paracentesis**

## Peritoneovenous shunt

### Definition

A peritoneovenous shunt refers to the surgical insertion of a shunting tube to achieve the continuous emptying of ascitic fluid into the venous system.

### Purpose

Ascites is a serious medical disorder characterized by the pathological accumulation of fluid in the peritoneal cavity, the smooth membrane that lines the cavity of the abdomen and surrounds the organs. Ascites is usually related to acute and chronic liver disease (cirrhosis) and to a lesser degree, to malignant tumors arising in the ovary, colon, or breast. Ascites may also be associated with chronic kidney disease and congestive heart failure. The formation of ascitic fluid results from the interplay of three factors: abnormally high pressure within the liver or the veins draining into the liver (portal hypertension); abnormally low amounts of albumin in the blood (hypoalbuminemia); and changes in sodium and water excretion by the kidneys.

When medical therapy fails, peritoneovenous shunts help manage chronic ascites.

### Demographics

Cirrhosis is the seventh leading cause of **death** by disease in the United States, killing over 25,000 people each year. Fifty percent of patients with cirrhosis will develop ascites over a period of 10 years. Cirrhosis—regardless of its cause—greatly increases the risk for liver cancer. Few studies have been conducted on the risk for liver cancer in patients with primary biliary cirrhosis; however, one study reported an incidence of 2.3%. Approximately 4% of patients with cirrhosis caused by hepatitis C develop liver cancer. In Asia, about 15% of people who have chronic hepatitis B develop liver cancer, but this high rate is not seen in other parts of the world. One Italian study that followed a group of hepatitis B patients for 11 years found no liver cancer over that period of time.

### Description

A variety of shunts have been designed for peritoneovenous shunting, including the Hyde shunt (1966-1974), LaVeen shunt (1974-1980), and Denver shunt. The latter predates the LaVeen shunt, but is more popular as of 2003. All designs work about equally well.

For the peritoneovenous shunt insertion procedure, the patient only requires a local anesthetic and a sedative. A long needle is inserted into the jugular vein in the neck, and is passed down through the superior vena cava, the large vein that delivers blood from the head, neck, and upper limbs back to the heart. This serves to widen the vein. The surgeon makes an incision and inserts a tube traversing the subcutaneous tissue of the chest wall. The tube connects the peritoneal cavity to the neck, where it enters the widened jugular vein. There the surgeon attaches a pressure-sensitive, one-way valve to prevent backflow.

### Diagnosis/Preparation

Ascites may go unnoticed for quite some time until the patient notices a slight increase in waistline. Severe ascites with marked abdominal distension becomes very disabling, especially when associated with swelling of the legs, pleural effusions (fluid around the lungs), and shortness of breath.

Diagnosis can be established by examination of the ascitic fluid, which allows the physician to differentiate between cirrhosis and tumor-induced ascites. The fluid is taken from the peritoneal cavity in a procedure called a **paracentesis**. Ascitic fluid analysis

## KEY TERMS

**Ascites**—An effusion and accumulation of serous fluid in the abdominal cavity.

**Ascitic fluid**—The fluid that accumulates in the peritoneal cavity in ascites.

**Coagulopathy**—A defect in the blood clotting mechanism.

**Edema**—The presence of abnormally large amounts of fluid in the intercellular tissue spaces of the body.

**Inferior vena cava**—Large vein that returns blood from the lower part of the body to the heart.

**Jugular vein**—Major vein of the neck that returns blood from the head to the heart.

**Hypoalbuminemia** —An abnormally low concentration of albumin in the blood.

**Paracentesis**—Surgical puncture of the abdominal cavity for the aspiration of peritoneal fluid.

**Peritoneal cavity**—The space enclosed by the peritoneum.

**Peritoneum**—The smooth membrane that lines the cavity of the abdomen, and surrounds the viscera, forming a closed sac.

**Portal hypertension**—Abnormally high pressure within the veins draining into the liver.

**Subcutaneous**—Beneath the skin.

**Superior vena cava**—Large vein that returns blood to the heart from the head, neck, and upper limbs.

**Venous system**—Circulation system that carries blood that has passed through the capillaries of various tissues, except the lungs, and is found in the veins, the right chambers of the heart, and the pulmonary arteries; it is usually dark red as a result of a lower oxygen content.

includes a total polymorph count, protein and albumin concentrations, and placement of at least 10 ml of ascitic fluid each into **blood culture** bottles for processing. If a measurement called the serum-ascitic fluid albumin gradient is greater than 11 g/L, cirrhosis, not cancer, is suspected.

## Aftercare

After surgery, the patient's **vital signs** are monitored in a **recovery room**. Pain medication and **antibiotics** are administered as needed. Once released from the hospital, the patient is expected to abstain

from alcohol, and follow a low-salt diet and medication regime designed to control ascites.

Patients also require training in shunt maintenance. To keep the fluid moving out of the abdomen, the shunt has to be properly pumped on a daily basis. Twice a day—once at bedtime and again prior to rising in the morning—the shunt is pumped about 20 times. This is essential to limit the accumulation of fibrin and other debris within the shunt, and to avoid the formation of an occlusive fibrin sheath at the venous tip.

## Risks

Complications following peritoneovenous shunt insertion are common and include infection, leakage of ascitic fluid, accumulation of abnormally large amounts of fluid in the intercellular tissue spaces of the body (edema), deregulation of the blood clotting mechanism (coagulopathy), and shunt blockage. Clogging of the shunt with debris is the most common complication. Some patients develop further complications from the ascitic fluid entering directly into their bloodstream. Scar tissue often develops, making future liver transplants difficult.

## Normal results

In spite of the complications associated with the procedure, many patients obtain useful relief from ascites following peritoneovenous shunt insertion.

## Morbidity and mortality rates

The most recent guidelines from the American Association for the Study of Liver Diseases recommend peritoneovenous shunting only under these conditions:

- Patient is diuretic-resistant and not a transplant candidate.
- Patient is not a candidate for serial therapeutic paracentesis because of multiple abdominal surgical scars.
- A physician is unavailable to perform serial paracentesis.

Cirrhosis is irreversible, but the rate of progression can be very slow depending on its cause and other factors. Five-year survival rates are about 85% in the United States and can be lower or higher depending on severity.

## Alternatives

Alternative treatments for ascites include:

- Diuretics. Diuretics are medications that promote the excretion of urine and help eliminate excess fluids. The treatment of ascites always involves restricting dietary

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

Peritoneovenous shunt insertion is performed in a hospital by a surgeon specialized in gastroenterology or hepatology.

- salt and taking diuretic pills to increase the output of salt in the urine. This treatment is effective, at least in the short-term, in 90% of patients.
- Repeated large-volume paracentesis. This approach, also called serial paracentesis, features repeated surgical puncture of the abdominal cavity and aspiration of the ascitic fluid.
  - Transjugular portosystemic shunt. A shunting procedure designed to relieve portal hypertension.
  - Portocaval shunt. Another shunting procedure designed to relieve portal hypertension.
  - Liver transplantation. Replacement of the patient's liver by one obtained from a donor. Liver transplantation is the only definitive treatment for ascites, and the only treatment that has been clearly shown to improve survival.

There is no satisfactory treatment for refractory ascites in patients with cirrhosis. Both peritoneovenous shunts and paracentesis have been used, but there is uncertainty about their relative merits.

## pH monitoring

### Definition

pH is a value that represents the balance of acidic and alkaline molecules in a given system. The human body requires a very precise balance between these in order to properly maintain homeostasis. Homeostasis, or physiological equilibrium, is the maintenance of stable conditions for bodily function. pH monitoring is the practice of keeping track of where the pH value

lies in order to quickly diagnose and treat disorders that alter pH.

### Description

pH monitoring is done to guard against physiological states in which the amount of acidic or alkaline molecules in the body is out of balance. Another term for acidic and alkaline is “acid and base”. Acid is represented in the body as hydrogen ions. Base is represented in the body as hydroxide ions. Too much of either one can cause serious physical harm. A pH scale is designed with the number seven falling in the middle, defined as neutral. At a pH of seven the amount of acid and base present lies in balance. Any pH greater than seven is considered more alkaline or basic. Any pH less than seven is considered more acidic. Each area of the body has its own normal range for pH. Human blood normally lies between a pH of 7.34 to 7.45. Human stomach acid normally lies between a pH of 1.5 to 2.0. Human urine normally has a pH of approximately 6.0.

A physiological state where the blood is too acidic with a low pH is called acidosis. Acidosis is caused by an imbalance in hydrogen ions present in the blood, causing the pH to fall below 7.35. On the other side of the scale, alkalosis is a physiological state where the blood pH value rises above 7.45 due an imbalance in hydroxide, and becomes too basic. The farther the pH is altered from the normal range, the more serious the patient’s condition. Even relatively small changes in blood pH can be life threatening. Blood pH values generally considered compatible with mammalian life lie between a pH of 6.8 to 7.8. For this reason, the body uses blood as a buffering system to maintain pH balance. Certain states of disease, disorders, or physical conditions sometimes overwhelm the body’s buffering systems and medical assistance becomes necessary to maintain life. In these cases, pH monitoring is a critical tool in guarding against or treating drastic alterations in body chemistry.

### Monitoring pH for Acidosis

Acidosis is physiological state of excessive acid in the blood. Acidosis can be caused by an increase in acid, or simply a decrease of base, causing what is known as metabolic acidosis. Acidosis can also be caused by abnormal respiratory function. Taking in too much carbon dioxide or too little oxygen through the lungs leads to increased amounts of carbon dioxide in the blood. Carbon dioxide in the blood is changed into multiple components, resulting in the release of hydrogen ions, causing acidosis. The type of acidosis originally caused by carbon dioxide and respiratory functioning is known as respiratory acidosis.

If an increase in acid or decrease in base occurs beyond the body’s pH buffering capabilities, there are other compensatory mechanisms to restore equilibrium in pH. In response to a drop in blood pH, the brain causes a change in respiration for fast, deep breathing. This type of breathing causes an increased amount of carbon dioxide to be exhaled, drawing more and more carbon dioxide from the blood. The more carbon dioxide leaves the blood, the more hydrogen ions are removed, helping to correct acidosis. Additionally, the kidneys may increase excretion of hydrogen ions or decrease excretion of hydroxide ions in the urine. Even with these compensatory mechanisms, a severe state of acidosis often requires medical attention to correct, with pH monitoring as a critical tool for health management. Without proper medical attention the acidotic patient may experience nausea, vomiting, fatigue, confusion, weakness, shock, coma, or **death**. The treatment of acidosis is dependent on the cause of the disorder.

### Conditions that Potentially Cause Acidosis and May Require pH Monitoring

- Ingestion of Wood Alcohol or Antifreeze (excessive acid)
- Aspirin Overdose (excessive acid)
- Poorly Controlled Diabetes (excessive acid)
- Kidney Dysfunction or Failure (cannot excrete acid normally)
- Lung Dysfunction (cannot expel carbon dioxide normally; e.g., severe pneumonia, emphysema, or asthma)
- Drugs that Disrupt Respiration (cannot expel carbon dioxide normally; e.g., narcotic pain-killer overdose)
- Ingestion of Acidic Poisons (excessive acid)
- Extreme Diarrhea (expel excessive base)

### Monitoring pH for Alkalosis

Alkalosis is a physiological state of excessive base in the blood. Alkalosis can be caused by an increase in base, or a decrease of acid, causing what is known as metabolic alkalosis. Alkalosis can also be caused by abnormal respiratory function. Exhaling too much carbon dioxide leads to a decrease in carbon dioxide in the blood. A decrease in carbon dioxide in the blood leads to a decrease in hydrogen ions and a relative excess of hydroxide ions. This type of alkalosis is known as respiratory alkalosis. Respiratory alkalosis can be induced by hyperventilation, a type of breathing that is very rapid and deep and leads to expulsion of large amounts of carbon dioxide.

## KEY TERMS

**Acidosis**—A pathological state in which there is a relative excess of hydrogen ions in the arterial blood.

**Alkaline**—A basic substance with pH above 7.0.

**Alkalosis**—A pathological state in which there is a relative excess of hydroxide ions in the arterial blood.

**Anxiety Attack**—A disorder in which sudden feelings of dread, fear, and apprehension of danger enter a person's mind in an overwhelming manner. Attacks may lead to a state of hyperventilation.

**Arterial Blood**—Blood from the arteries, the blood vessels that carry oxygen from the lungs to supply the body tissues.

**Arterial Blood Gas (ABG)**—A type of blood laboratory test done to check the blood for imbalances in pH or gases that affect pH.

**Asthma**—An inflammatory respiratory disorder in which the airway becomes obstructed and breathing is difficult.

**Coronary Artery Bypass Surgery**—A surgical procedure where arteries or veins from elsewhere in the patient's body grafted into the arteries of the heart as a way to bypass damaged or narrowed heart blood vessels. Heart blood vessels may have been damaged or narrowed from fat deposition and need to be bypassed to increase the blood supply and oxygen delivered to the heart.

**Corticosteroid**—A type of drug used to treat inflammatory conditions that also alters blood ions and affects pH.

**Diuretic**—A type of drug used to treat hypertension that also alters blood ions and affects pH.

**Electrode**—A device used to record an electric circuit or changes in ion concentrations.

**Emphysema**—Lung disease that causes damage to lung tissue and breathlessness.

**Heart Lung Machine**—A machine that temporarily takes over the function of the heart and lungs during surgical procedures in order to maintaining blood circulation and delivery of oxygen to body tissues while the heart is being operated on.

**Heart Valve Replacement Surgery**—Surgery performed to repair or replace the valves in the heart that control blood flow through the heart and are responsible for the audible heartbeat.

**Homeostasis**—The process of maintaining balance in the normal vital life functions of a living organism.

**Hydrogen Ions**—Ions that contain one hydrogen atom with a positive charge. Hydrogen ions cause blood to be acidic.

**Hydroxide Ions**—Ions that contain one oxygen and one hydrogen atom, with a negative charge. Hydroxide ions cause blood to be alkaline.

**Ischemia**—A state of decreased oxygen, where body tissues may experience damage due to oxygen deprivation.

**Narcotic Pain Killer**—A type of pain killer often used after surgical procedures that may alter blood pH.

**Physiological**—Pertaining to the normal vital life functions of a living organism.

**Pneumonia**—An inflammatory lung disease that affects the ability of the respiratory system to function.

**Radial Artery**—An artery present in the wrist that is convenient for drawing blood intended for laboratory testing.

**Respiratory Function**—The ability of the breathing structures of the body, including the lungs, to function.

**Venous Blood**—Blood that carries carbon dioxide from the tissues to the heart and then the lungs to be oxygenated.

If an increase in base or decrease in acid occurs beyond the body's pH buffering capabilities, compensatory mechanisms to restore equilibrium in pH include a change in respiration for slow, shallow breathing. This type of breathing causes a decreased amount of carbon dioxide to be exhaled, thereby increasing the amount of carbon dioxide and hydrogen ions in the blood. Additionally, the kidneys may increase excretion of hydroxide ions or decrease excretion of hydrogen ions in the urine. Similar to acidosis,

a severe state of alkalosis often requires medical attention to correct, with pH monitoring as a critical tool for health management. Without proper medical attention the patient may experience irritability, muscle cramping, muscle spasms, seizures, delirium, and death. The treatment of alkalosis is dependent on the cause of the disorder.

Conditions that Potentially Cause Alkalosis and May Require pH Monitoring

- Prolonged Vomiting (loss of excessive acid)
- Ingestion of Alkaline Poisons (excessive base)
- Drugs that Cause Excessive Loss of Sodium or Potassium Ions (e.g., diuretics and corticosteroids)
- Severe Anxiety Attacks (hyperventilation)
- Pain and Fever (hyperventilation)
- Aspirin Overdose (Aspirin can cause both acidosis and alkalosis)

### How pH is Monitored

pH is monitored through laboratory tests done on the blood drawn from an artery. Arterial blood is an accurate indicator of blood pH. Venous blood holds too much carbon dioxide taken from the tissues to be useful. Blood is usually taken from the radial artery located in the wrist. The blood is tested for pH, as well as levels of carbon dioxide and other pertinent blood components. The laboratory test is known as Arterial Blood Gas (**ABG**). It is very important that room air is not accidentally introduced into the sample of blood drawn, as the oxygen present would make the blood unsuitable for testing. If the patient's condition warrants it, the ABG test may be done several times a day.

### pH Monitoring during Heart Surgery

Some types of heart surgery involve temporarily depriving parts of the heart of its blood supply during the procedure (while the patient is on a heart lung machine to maintain bodily function). Local blood deprivation results in decreased heart tissue oxygen (a condition called ischemia), increased tissue carbon dioxide levels, heart tissue acidosis, and possibly death of heart tissue. The level to which this actually occurs during the procedure varies from person to person. The severity of tissue acidosis has been shown to directly associate with the degree of ischemia that tissue is experiencing and consequent impact on long-term survival of the surgery patient.

Specific low pH values during different points in the surgical procedure have been identified as dangerous levels of acidosis. Allowing the heart tissue to fall below these values may be associated with post-operative heart failure and mortality. Purposefully raising the pH levels before these specific points in the procedure, prior to heart tissue ischemia and a drop in pH, may help keep the heart tissue pH above dangerous levels of acidosis and ischemia. Special intraoperative heart pH monitors have been designed to supervise the pH value of heart tissue during surgery and keep track of the surgeon's efforts in pH modification. Electrodes designed as sterile probes that detect pH are inserted directly into the heart and used as an early warning

system for dangerous changes in pH. Surgical procedures that may be benefited by pH monitors include heart valve replacement surgery and coronary artery bypass surgery. pH monitoring is an important tool for surgeons to avoid or reverse acidosis and ischemia during heart surgery, thereby improving long-term patient survival.

Maria Basile, PhD

## Phacoemulsification for cataracts

### Definition

Phacoemulsification cataract surgery is a procedure in which an ultrasonic device is used to break up and then remove a cloudy lens, or cataract, from the eye to improve vision. The insertion of an intraocular lens (IOL) usually immediately follows phacoemulsification.

### Purpose

Phacoemulsification, or phaco, as surgeons refer to it, is used to restore vision in patients whose vision has become cloudy from cataracts. In the first stages of a cataract, people may notice only a slight cloudiness as it affects only a small part of the lens, the part of the eye that focuses light on the retina. As the cataract grows, it blocks more light and vision becomes cloudier. As vision worsens, the surgeon will recommend cataract surgery, usually phaco, to restore clear vision. With advancements in cataract surgery such as the IOL patients can sometimes experience dramatic vision improvement.

In a phacoemulsification procedure, an incision is first made in the cornea, the outer covering of the eye (A). A phacoemulsification instrument uses ultrasonic waves to break up the cataract (B). Pieces of the cataract are then suctioned out (C). To repair the patient's vision, a folded intraocular lens is pushed through the same incision (D) and opened in place (E). (Illustration by GGS Information Services. Cengage Learning, Gale.)

## Demographics

As people age, cataracts are likely to form. The National Eye Institute (NEI) reports in a 2002 study that more than half of all United States residents 65 and older have a cataract. People who smoke are at a higher risk for cataracts. Increased exposure to sunlight or infrared radiation without eye protection may also be a cause.

Cataracts also can occur anytime because of injury, exposure to toxins, or such diseases as diabetes. Congenital cataracts are caused by genetic defects or developmental problems, or exposure to some contagious diseases during pregnancy.

However, the most common form of cataract in the United States is age-related. According to the NEI, cataracts are more common in women than in men, and Caucasians have cataracts more frequently than other races, especially as people grow older. People

who live close to the equator also are at higher risk for cataracts because of increased sunlight exposure. Heavy alcohol consumption is also a risk factor for cataract formation.

More than 2.5 million cataract surgeries are performed in the United States each year. The NEI reports that the federal government, through **Medicare**, spends more than \$3.4 billion each year treating cataracts. Cataract surgery is one of the most common surgeries performed, and also one of the safest and most effective. Phaco is currently the most popular version of cataract surgery.

## Description

Phacoemulsification is a variation of **extracapsular cataract extraction (ECCE)**, a procedure in which the lens and the front portion of the capsule are removed. Formerly the most popular cataract surgery,

## KEY TERMS

**Astigmatism**—Asymmetric vision defects due to irregularities in the cornea.

**Capsulorrhexis**—The creation of a continuous circular tear in the front portion of the lens capsule during cataract surgery to allow for removal of the lens nucleus.

**Cornea**—Clear, bowl-shaped structure at the front of the eye. It is located in front of the colored part of the eye (iris). The cornea lets light into the eye and partially focuses it.

**Floaters**—Spots in the field of vision.

**Glaucoma**—Disease of the eye characterized by increased pressure of the fluid inside the eye. Untreated, glaucoma can lead to blindness.

**Lens (the crystalline lens)**—A transparent structure in the eye that focuses light onto the retina.

**Myopia**—A refractive error that causes distant objects to appear blurry. Myopia results when light does not focus properly on the retina.

**Retina**—The inner light-sensitive layer of the eye containing rods and cones.

the older method of extracapsular extraction involves a longer incision, about 0.4 in (10 mm), or almost half the length of the eye. Recovery from the larger incision used for extracapsular extraction also requires almost a week-long hospital stay after surgery, and limited physical activity for weeks or even months.

Dr. Charles Kelman (1930–2004) introduced the technique of phacoemulsification in the late 1960s. He was inspired by his dentist's use of ultrasonic tools. His goal was to remove the cataract with a smaller incision, less pain, and shorter recovery time. He discovered that the cataract could be broken up, or emulsified, into small pieces using an **ultrasound** tip. At first, phaco was slow to catch on because of its high learning curve. With its success rate and shorter recovery period, surgeons slowly learned the technique. Over the past decades, surgeons have constantly refined phaco to make it even safer and more successful. Innovations in technology such as the foldable IOL also have helped improve outcomes by allowing surgeons to make smaller incisions.

During surgery, the patient will probably breathe through an oxygen tube because it might be difficult to breathe with the draping. The patient's blood pressure and heart rate also are likely to be monitored.

Before making the incision, the surgeon inserts a long needle, usually through the lower eyelid, to anesthetize the area behind the eyeball. The surgeon then puts pressure on the eyeball with his or her hand or a weight to see if there is any bleeding (possibly caused by inserting the anesthetic). The pressure will stop this bleeding. This force also decreases intraocular pressure (IOP), which lowers the chances of complications.

After applying the pressure, the surgeon looks through a microscope and makes an incision about 0.1 in (3 mm) on the side of the anesthetized cornea. As of 2003, surgeons are beginning to favor the temporal location for the incision because it has proved to be safer. The incision site also varies depending on the size and denseness of the cataract. Once the incision is made, a viscoelastic fluid is injected to reduce shock to the intraocular tissues. The surgeon then makes a microscopic circular incision in the membrane that surrounds the cataract; this part of the procedure is called capsulorrhexis. A water stream then frees the cataract from the cortex. The surgeon inserts a small titanium needle, or phaco tip, into the cornea. The ultrasound waves from the phaco tip emulsify the cataract so that it can be removed by suction. The surgeon first focuses on the cataract's central nucleus, which is denser than the rest of the cataract.

While the cataract is being emulsified, the machine simultaneously aspirates the cataract through a small hole in the tip of the phaco probe. The surgeon then removes the cortex of the lens, but leaves the posterior capsule, which is used to support the intraocular lens.

The folded IOL is inserted by an injector. The folded IOL means that a larger incision is not required. After the IOL is inserted into the capsular bag, the viscoelastic fluid is removed. No sutures are usually required after the surgery. Some surgeons may recommend that patients wear an eye shield immediately after the surgery.

The entire procedure takes between 15 and 20 minutes. The phaco procedure itself takes only a few minutes.

Most surgeons prefer a certain technique for the procedure, although they might vary due to the cataract's density and size. The variations on the phaco procedure lie mostly on what part of the nucleus the surgeon focuses on first, and how the cataract is emulsified. Some surgeons prefer a continuous "chop," while others divide the cataract into quadrants for removal. One procedure, called the "phaco flip," involves the surgeon inverting and then rotating the lens for removal. Advances in technology also may allow for even smaller incisions, some speculate as small as 0.05 in (1.4 mm).

## Diagnosis/Preparation

People may have cataracts for years before vision is impaired enough to warrant surgery. Eye doctors may first suggest eyeglasses to temporarily help improve vision. But as the lens grows cloudier, vision deteriorates.

As cataracts develop and worsen, patients may notice these common symptoms:

- gradual (and painless) onset of blurry vision
- poor central vision
- frequent changes in prescription for corrective lenses
- increased glare from lights
- near-vision improvement to the point where reading glasses may no longer be needed
- poor vision in sunlight

Cataracts grow faster in younger people or in patients with diabetes, so doctors will recommend surgery more quickly in those cases. Surgery may also be recommended sooner if the patient suffers from such other eye diseases as age-related macular degeneration and the cataract interferes with complete eye examination.

When symptoms worsen to the point that everyday activities become problematic, surgery becomes necessary. A complete ocular exam will determine the severity of the cataract and what type of surgery the patient will receive. For some denser cataracts, the older method of extracapsular extraction is preferred.

The diagnostic examination should include measurement of visual acuity under both low and high illumination, microscopic examination of eye structures and pupil dilation, assessment of visual fields, and measurement of intraocular pressure (IOP).

If cataracts are detected in both eyes, each eye must be treated separately.

The patient's overall health must also be considered, and how it will affect the surgery's outcome. Surgeons may recommend a complete **physical examination** before surgery.

Although preoperative instructions may vary, patients are usually required not to eat or drink anything after midnight the day of the surgery. Patients must disclose all medications to determine if they must be discontinued before surgery. Patients taking **aspirin** for blood thinning usually are asked to stop for two weeks before surgery. Blood-thinning medications may put patients at risk for intraocular bleeding or hemorrhage. Coumadin, the prescription medicine for blood thinning, might still be taken if the risk for

stroke is high. People should consult with their eye doctor and internist to decide the best course of action.

An A-scan measurement, which determines the length of the eyeball, will be performed. This test helps to determine the refractive power of the IOL. Other pre-surgical testing such as a **chest x ray**, blood work, or **urinalysis** may be requested if other medical problems are an issue.

The surgeon may also request patients begin using antibiotic drops before the surgery to limit the chance of infection.

Cataract surgery is done on an outpatient basis, so patients must arrange for someone to take them home after surgery. On the day of the surgery, doctors will review the pre-surgical tests and insert dilating eye drops, antibiotic drops, and a corticosteroid or non-steroidal anti-inflammatory drop. Anesthetic eye drops will be given in both eyes to keep both eyes comfortable during surgery. A local anesthetic will be administered. Patients are awake for the surgery, but are kept in a relaxed state.

The patient's eye is scrubbed prior to surgery and sterile drapes are placed over the shoulders and head. The patient is required to lie still and focus on the light of the operating microscope. A speculum is inserted to keep the eyelids open.

## Aftercare

Immediately following surgery, the patient is monitored in an outpatient recovery area. The patient is advised to rest for at least 24 hours, until he or she returns to the surgeon's office for follow-up. Only light meals are recommended on the day of surgery. The patient may still feel drowsy and may experience some eye pain or discomfort. Usually, over-the-counter medications are advised for pain relief, but patients should check with their doctors to see what is recommended. Such other side effects as severe pain, nausea, or vomiting should be reported to the surgeon immediately.

There will be some changes in the eye during recovery. Patients may see dark spots, which should disappear a few weeks after surgery. There also might be some discharge and itching of the eye. Patients may use a warm, moist cloth for 15 minutes at a time for relief and to loosen the discharge. All matter from the discharge should be gently cleared away with a tissue, not a fingertip. Pain and sensitivity to light are also experienced after surgery. Some patients may also have slight drooping or bruising of the eye which will improve as the eye heals.

Patients have their first postoperative visit the day after surgery. The surgeon will remove the eye shield and prescribe eye drops to prevent infections and control intraocular pressure. These eye drops are used for about a month after surgery.

Patients are advised to wear an eye shield while sleeping, and refrain from rubbing the eye for at least two weeks. During that time, the doctor will give the patient special tinted sunglasses or request that he or she wear current prescription eyeglasses to prevent possible eye trauma from accidental rubbing or bumping. Unlike other types of cataract extraction, patients can resume normal activity almost immediately after phaco.

Subsequent exams are usually at one week, three weeks, and six to eight weeks following surgery. This can change, however, depending on any complications or any unusual postoperative symptoms.

After the healing process, the patient will probably need new corrective lenses, at least for close vision. While IOLs can remove the need for myopic correction, patients will probably need new lenses for close work.

### Risks

Complications are unlikely, but can occur. Patients may experience spontaneous bleeding from the wound and recurrent inflammation after surgery. Flashing, floaters, and double vision may also occur a few weeks after surgery. The surgeon should be notified immediately of these symptoms. Some can easily be treated, while floaters may be a sign of retinal detachment.

Retinal detachment is one possible serious complication. The retina can become detached by the surgery if there is any weakness in the retina at the time of surgery. This complication may not occur for weeks or even years; one study reported in 2006 that patients who have had cataracts removed by phaco have an increased risk of retinal detachment 20 years after surgery.

Infections are another potential complication, the most serious being endophthalmitis, which is an infection in the eyeball. This complication, once widely reported, is much more uncommon today because of newer surgery techniques and **antibiotics**.

Patients may also be concerned that their IOL might become displaced, but newer designs of IOLs also have limited reports of intraocular lens dislocation.

Other possible complications are the onset of glaucoma and, in very rare cases, blindness.

It is possible that a secondary cataract may develop in the remaining back portion of the capsule. This can occur for as long as one to two years after surgery. YAG capsulotomy, using a laser, is most often

used for the secondary cataract. This outpatient procedure requires no incision. The laser makes a small opening in the remaining back part of the lens to allow light to penetrate.

### Normal results

Most patients have restored visual acuity after surgery, and some will have the best vision of their lives after the insertion of IOLs. Some patients will no longer require the use of eyeglasses or contact lenses after cataract surgery. Patients will also have better color and depth perception and be able to resume normal activities they may have stopped because of impaired vision from the cataract, such as driving, reading, or sports.

### Morbidity and mortality rates

Phacoemulsification has lowered the previous risks from cataract surgery, making it a much safer procedure. Before phacoemulsification, **death** after cataract surgery was still rare, but usually stemmed from the possible complications of **general anesthesia**. Phaco is performed under **local anesthesia**, eliminating the risk of general anesthetic use.

Other serious complications such as blindness also have been reduced with the widespread use of phaco. Newer antibiotics have enabled physicians to combat former debilitating infections that previously would have caused blindness.

### Alternatives

Some older methods of cataract surgery may have to be used if the cataract is too large to remove with a small incision, including:

- Extracapsular cataract extraction (ECCE). While phaco is considered a type of extracapsular extraction, the older version of this technique requires a much larger incision and does not use the phaco machine. It is similar in that the lens and the front portion of the capsule are removed and the back part of the capsule remains. The surgeon might consider this technique if the patient has corneal disease or if the pupil becomes too small during the first stages of surgery. While standard ECCE and phacoemulsification have similar success rates and complication rates when performed by surgeons of comparable skill and length of experience, a meta-analysis of 17 trials of these two methods reported in 2006 that phacoemulsification gives a better long-term outcome than standard ECCE with sutures.

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

Ophthalmologists and optometrists may detect cataracts; however, only an ophthalmologist can perform cataract surgery. An anesthesiologist may be on hand during surgery to administer the local anesthetic. Surgical nurses will assist the ophthalmologist in the operating room and assist the patient preoperatively and postoperatively.

The outpatient surgery is performed in a hospital or surgery suite designed for ophthalmic surgery.

- Intracapsular cataract extraction (ICCE). This technique also requires a larger incision than phaco. It differs in that the lens and the entire capsule are removed. While ICCE is the easiest cataract surgery for the surgeon technically, this method carries an increased risk for the patient with increased potential for detachment of the retina and swelling after surgery. Recovery is long and most patients will have to use large “cataract glasses” to see.

## QUESTIONS TO ASK THE DOCTOR

- Will Medicare pay for the surgery and my aftercare?
- If I have a cataract in the other eye, how long must I wait to have the other eye treated?
- Will I still need reading glasses after surgery? Will I still need eyeglasses to see far away even if you insert an intraocular lens?
- How many cataract surgeries have you performed? How many of these have been phacoemulsification?
- What precautions should I take to protect my eye after surgery?
- When can I resume my normal activities after surgery? Contact sports?

## Pharyngectomy

### Definition

A pharyngectomy is the total or partial surgical removal of the pharynx, the cavity at the back of the mouth that opens into the esophagus at its lower end.

The pharynx is cone-shaped, has an average length of about 3 in (76 mm), and is lined with mucous membrane.

### Purpose

A pharyngectomy procedure is performed to treat cancers of the pharynx that include:

- **Throat cancer.** Throat cancer occurs when cells in the pharynx or larynx (voice box) begin to divide abnormally and out of control. A total or partial pharyngectomy is usually performed for cancers of the hypopharynx (last part of the throat), in which all or part of the hypopharynx is removed.
- **Hypopharyngeal carcinoma (HPC).** A carcinoma is a form of cancerous tumor that may develop in the pharynx or adjacent locations and for which surgery may be indicated.

### Description

Whether a pharyngectomy is performed in total or with only partial removal of the pharynx depends on the localized amount of cancer found. The procedure may also involve removal of the larynx, in which case it is called a laryngopharyngectomy. Well-localized, early stage HPC tumors can be amenable to a partial pharyngectomy or a laryngopharyngectomy, but laryngopharyngectomy is more commonly performed for more advanced cancers. It can be total, involving removal of the entire larynx, or partial and may also involve removal of part of the esophagus (esophagectomy). Patients undergoing laryngopharyngectomy will lose some speaking ability and require special techniques or reconstructive procedures to regain the use of their voice.

Following a total or partial pharyngectomy, the surgeon may also need to reconstruct the throat so that the patient can swallow. A **tracheotomy** is used when the tumor is too large to remove. In this procedure, a hole is made in the neck to bypass the tumor and allow the patient to breathe.

For this type of surgery, patient positioning requires access to the lower part of the neck for the surgeon. This is conveniently achieved by placing the patient on a table fitted with a head holder, allowing the head to be bent back but well supported.

If a laryngopharyngectomy is performed, the surgeon starts with a curved horizontal neck skin incision. The **laryngectomy** incision is usually made from the breastbone to the lower most of the laryngeal cartilages, such that a 1–2 in (2.54–5.08 cm) bridge of skin is preserved. Once the incision is deepened, flaps are elevated until the larynx is exposed. The anterior jugular veins and strap muscles are left undisturbed. The

sternocleidomastoid muscle is then identified. The layer of cervical fibrous tissue is cut (incised) longitudinally from the hyoid (the bony arch that supports the tongue) above to the clavicle (collarbone) below. Part of the hyoid is then divided, which allows the surgeon to enter the loose compartment bounded by the sternomastoid muscle and carotid sheath (which covers the carotid artery) and by the pharynx and larynx in the neck. The pharyngectomy incisions and laryngeal removal are performed, and a view of the pharynx is then possible. Using scissors, the surgeon performs bilateral (on both sides), direct cuts, separating the pharynx from the larynx. If a preliminary tracheotomy has not been performed, the oral endotracheal tube is withdrawn from the tracheal stump and a new, cuffed, flexible tube inserted for connection to new anesthesia tubing. The wound is thoroughly irrigated (flushed); all clots are removed; and the wound is closed. The pharyngeal wall is closed in two layers. The muscle layer closure always tightens the opening to some extent and is usually left undone at points where narrowing may be excessive. In fact, studies show that a mucosal (inner layer) closure alone is sufficient for proper healing.

### Diagnosis/Preparation

The initial **physical examination** for a pharyngectomy usually includes examination of the neck, mouth, pharynx, and larynx. A neurologic examination is sometimes also performed. Laryngoscopy is the examination of choice, performed with a long-handled mirror, or with a lighted tube called a laryngoscope. A local anesthetic might be used to ease discomfort. A MRI of the oral cavity and neck may also be performed.

If the physician suspects throat cancer, a biopsy will be performed—this involves removing tissue for examination in the laboratory under a microscope. Throat cancer can only be confirmed through a biopsy or using fine needle aspiration (FNA). The physician also may use an imaging test called a computed tomography (CT) scan. This is a special type of x ray that provides images of the body from different angles, allowing a cross-sectional view. A CT-scan can help to find the location of a tumor, to judge whether or not a tumor can be removed surgically, and to determine the cancer's stage of development.

Before surgery, the patient is also examined for nutritional assessment and supplementation, and careful staging of cancer, while surgical airway management is planned with the anesthesiologist such that a common agreement is reached with the surgeon concerning the timing of tracheotomy and intubation.

## KEY TERMS

**Anesthesia**—A combination of drugs administered by a variety of techniques by trained professionals that provide sedation, amnesia, analgesia, and immobility adequate for the accomplishment of the surgical procedure with minimal discomfort, and without injury, to the patient.

**Biopsy**—Procedure that involves obtaining a tissue specimen for microscopic analysis to establish a precise diagnosis.

**Carcinoma**—A malignant growth that arises from epithelium, found in skin or, more commonly, the lining of body organs.

**Computed tomography (CT) scan**—An imaging technique that creates a series of pictures of areas inside the body, taken from different angles. The pictures are created by a computer linked to an x-ray machine.

**Dysphagia**—Difficulty in eating as a result of disruption in the swallowing process. Dysphagia can be a serious health threat because of the risk of aspiration pneumonia, malnutrition, dehydration, weight loss, and airway obstruction.

**Esophagectomy**—Surgical removal of the esophagus.

**Esophagus**—A long hollow muscular tube that connects the pharynx to the stomach.

**Fine needle aspiration (FNA)**—Technique that allows a biopsy of various bumps and lumps. It allows the

otolaryngologist to retrieve enough tissue for microscopic analysis and thus make an accurate diagnosis of a number of problems, such as inflammation or cancer.

**Fistula**—An abnormal passage or communication, usually between two internal organs or leading from an internal organ to the surface of the body.

**Hypopharynx**—The last part of the throat or the pharynx.

**Laryngopharyngectomy**—Surgical removal of both the larynx and the pharynx.

**Laryngoscopy**—The visualization of the larynx and vocal cords. This may be done directly with a fiberoptic scope (laryngoscope) or indirectly with mirrors.

**Laryngectomy**—Surgical removal of the larynx.

**Larynx**—Voice box.

**Magnetic resonance imaging (MRI)**—A procedure in which a magnet linked to a computer is used to create detailed pictures of areas inside the body.

**Pharynx**—The cavity at the back of the mouth. It is cone shaped and has an average length of about 3 in (76 mm) and is lined with mucous membrane. The pharynx opens into the esophagus at the lower end.

**Tracheotomy**—Opening of the trachea (windpipe) to the outside through a hole in the neck.

The anesthesiologist may elect to use an orotracheal (through the mouth and trachea) tube with anesthetic, which can be removed if a subsequent tracheotomy is planned.

### Aftercare

After undergoing a pharyngectomy, special attention is given to the patient's pulmonary function and fluid/nutritional balance, as well as to local wound conditions in the neck, thorax, and abdomen. Regular postoperative checks of calcium, magnesium, and phosphorus levels are necessary; supplementation with calcium, magnesium, and 1,25-dihydroxycholecalciferol is usually required. A patient may be unable to take in enough food to maintain adequate nutrition and experience difficulty eating (dysphagia). Sometimes it may be necessary to have a feeding tube placed through the skin and muscle of the abdomen directly

into the stomach to provide extra nutrition. This procedure is called a **gastrostomy**.

**Reconstructive surgery** is also required to rebuild the throat after a pharyngectomy in order to help the patient with swallowing after the operation. Reconstructive surgeries represent a great challenge because of the complex properties of the tissues lining the throat and underlying muscle that are so vital to the proper functioning of this region. The primary goal is to re-establish the conduit connecting the oral cavity to the esophagus and thus retaining the continuity of the alimentary tract. Two main techniques are used:

- **Myocutaneous flaps.** Sometimes a muscle and area of skin may be rotated from an area close to the throat, such as the chest (pectoralis major flap), to reconstruct the throat.
- **Free flaps.** With the advances of microvascular surgery (sewing together small blood vessels under a microscope), surgeons have many more options to

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

A pharyngectomy is major surgery performed by a surgeon trained in otolaryngology. An anesthesiologist is responsible for administering anesthesia and the operation is performed in a hospital setting. Otolaryngology is the oldest medical specialty in the United States. Otolaryngologists are physicians trained in the medical and surgical management and treatment of patients with diseases and disorders of the ear, nose, throat (ENT), and related structures of the head and neck. They are commonly referred to as ENT physicians.

With cancer involved in pharyngectomy procedures, the otolaryngologist surgeon usually works with radiation and medical oncologists in a treatment team approach.

reconstruct the area of the throat affected by a pharyngectomy. Tissues from other areas of the patient's body such as a piece of intestine or a piece of arm muscle can be used to replace parts of the throat.

### Risks

Potential risks associated with a pharyngectomy include those associated with any head and neck surgery, such as excessive bleeding, wound infection, wound slough, fistula (abnormal opening between organs or to the outside of the body), and, in rare cases, blood vessel rupture. Specifically, the surgery is associated with the following risks:

- Drain failure. Drains unable to hold a vacuum represent a serious threat to the surgical wound.
- Hematoma. Although rare, blood clot formation requires prompt intervention to avoid pressure separation of the pharyngeal repair and compression of the upper windpipe.
- Infection. A subcutaneous infection after total pharyngectomy is recognized by increasing redness and swelling of the skin flaps at the third to fifth post-operative day. Associated odor, fever, and elevated white blood cell count will occur.
- Pharyngocutaneous fistula. Patients with poor pre-operative nutritional status are at significant risk for fistula development.
- Narrowing. More common at the lower, esophageal end of the pharyngeal reconstruction than in the

## QUESTIONS TO ASK THE DOCTOR

- How will the surgery affect my ability to swallow and to eat?
- What type of anesthesia will be used?
- How long will it take to recover from the surgery?
- When can I expect to return to work and/or resume normal activities?
- To what extent will my ability to speak be affected?
- What are the risks associated with a pharyngectomy?
- How many pharyngectomies do you perform in a year?

upper end, where the recipient lumen of the pharynx is wider.

- Functional swallowing problems. Dysphagia is also a risk which depends on the extent of the pharyngectomy.

### Normal results

Oral intake is usually started on the seventh post-operative day, depending on whether the patient has had preoperative radiation therapy, in which case it may be delayed. Mechanical voice devices are sometimes useful in the early, post-operative phase, until the pharyngeal wall heals. Results are considered normal if there is no re-occurrence of the cancer at a later stage.

### Morbidity and mortality rates

Smokers are at high risk of throat cancer. According to the Harvard Medical School, throat cancer also is associated closely with other cancers: 15% of throat-cancer patients also are diagnosed with cancer of the mouth, esophagus, or lung. Another 10–20% of throat-cancer patients develop these other cancers later. Other people at risk include those who drink a lot of alcohol, especially if they also smoke. Vitamin A deficiency and certain types of human papillomavirus (HPV) infection also have been associated with an increased risk of throat cancer.

Surgical treatment for hypopharyngeal carcinomas is difficult as most patients are diagnosed with advanced disease, and five-year disease specific survival is only 30%. Cure rates have been the highest with surgical resection followed by postoperative radiotherapy. Immediate reconstruction can be accomplished with regional and free tissue transfers. These techniques have greatly reduced morbidity, and allow most patients to successfully resume an oral diet.

## Phlebography

### Definition

Phlebography is an x-ray test that provides an image of the leg veins after a contrast dye is injected into a vein in the patient's foot.

### Purpose

Phlebography is primarily performed to diagnose deep vein thrombosis—a condition in which clots form in the veins of the leg. Pulmonary embolism can occur when those clots break off and travel to the lungs and pulmonary artery. Phlebography can also be used to evaluate congenital vein problems, assess the function of the deep leg vein valves, and identify a vein for arterial bypass grafting. **Ultrasound** has replaced phlebography in many cases; but phlebography is the "gold standard," or the best test by which others are judged, even though it is not used routinely.

### Description

Phlebograph, (also called venography, ascending contrast phlebography, or contrast phlebography) is an invasive diagnostic test that provides a constant image of leg veins on a fluoroscope screen. Phlebography identifies the location and extent of blood clots, and enables the condition of the deep leg veins to be assessed. It is especially useful when there is a strong suspicion of deep vein thrombosis, after noninvasive tests have failed to identify the disease.

Phlebography is the most accurate test for detecting deep vein thrombosis. It is nearly 100% sensitive and specific in making this diagnosis. (Pulmonary embolism is diagnosed in other ways.) Accuracy is crucial since deep vein thrombosis can lead to pulmonary embolism, a potentially fatal condition.

Phlebography is not used often; however, because it is painful, expensive, time-consuming, exposes the patient to a fairly high dose of radiation, and can cause complications. In about 5% of cases, there are technical problems in conducting the test.

Phlebography takes 30–45 minutes, and can be done in a physician's office, a laboratory, or a hospital. During the procedure, the patient lies on a tilting x-ray table. The area where the catheter will be inserted is shaved, if necessary, and cleaned. In some cases, a local anesthetic is injected to numb the skin at the site of the insertion. A small incision may be required to make a point for insertion. The catheter is inserted and the contrast solution (or dye) is slowly

## KEY TERMS

**Contrast solution**—A liquid dye injected into the body that allows structures, including veins, to be seen by x rays. Without the dye, the veins could not be seen on x rays.

**Deep vein thrombosis**—The development or presence of a blood clot in a vein deep within the leg. Deep vein thrombosis can lead to pulmonary embolism.

**Invasive**—A diagnostic test that invades healthy tissue; in the case of phlebography, through an incision in a healthy vein.

**Pulmonary embolism**—An obstruction of a blood vessel in the lungs, usually due to a blood clot that blocks a pulmonary artery. A pulmonary embolism can be very serious and in some cases is fatal.

injected. Injection of the dye causes a warm, flushing feeling in the leg that may spread through the body. The contrast solution may also cause slight nausea. Approximately 18% of patients experience discomfort from the contrast solution.

In order to fill the deep venous system with dye, a tight band (tourniquet) may be tied around the ankle or below the knee of the side into which the dye is injected, or the lower extremities may be tilted. The patient is asked to keep the leg still. The physician observes the movement of the solution through the vein with a fluoroscope. At the same time, a series of x rays is taken. When the test is finished, fluid is injected to clear the contrast from the veins, the catheter is removed, and a bandage is applied over the injection site.

## Preparation

Fasting or drinking only clear liquids is necessary for four hours before the test, although the procedure may be done in an emergency even if the patient has eaten. The contrast solution contains iodine, to which some people are allergic. Patients should tell their physician if they have allergies or hay fever, or if they have had a reaction to a contrast solution.

## Aftercare

Patients should drink large amounts of fluids to flush the remaining contrast solution from their bodies. The area around the incision will be sore for a few days. The physician should be notified if there is

swelling, redness, pain, or fever. Pain medication is rarely needed. In most cases, the patient can resume normal activities the next day.

## Risks

Phlebography can cause complications such as phlebitis, tissue damage, and the formation of deep vein thrombosis in a healthy leg. A rare side effect in up to 8% of cases is a severe allergic reaction to the dye. This usually happens within 30 minutes after injection of the dye, and requires medical attention.

## Normal results

Normal phlebography results show proper blood flow through the leg veins.

Abnormal phlebography results show well-defined filling defects in veins. These findings confirm a diagnosis of deep vein thrombosis:

- blood clots
- consistent filling defects
- an abrupt end of a contrast column
- major deep veins that are unfilled
- dye flow that is diverted

## Phlebotomy

### Definition

Phlebotomy is the act of drawing or removing blood from the circulatory system through a cut (incision) or puncture in order to obtain a sample for analysis and diagnosis. Phlebotomy is also done as part of the patient's treatment for certain blood disorders.

### Purpose

Phlebotomy that is part of treatment (therapeutic phlebotomy) is performed to treat polycythemia vera, a condition that causes an elevated red blood cell volume (**hematocrit**). Phlebotomy is also prescribed for patients with disorders that increase the amount of iron in their blood to dangerous levels, such as hemochromatosis, hepatitis B, and hepatitis C. Patients with pulmonary edema may undergo phlebotomy procedures to decrease their total blood volume.

Phlebotomy is also used to remove blood from the body during **blood donation** and for analysis of the substances contained within it.

### Description

Phlebotomy is performed by a nurse or a technician known as a phlebotomist. Blood is usually taken from a vein on the back of the hand or just below the elbow. Some blood tests, however, may require blood from an artery. The skin over the area is wiped with an antiseptic, and an elastic band is tied around the arm. The band acts as a tourniquet, retaining blood within the arm and making the veins more visible. The phlebotomy technician feels the veins in order to select an appropriate one. When a vein is selected, the technician inserts a needle

**Preparing phlebotomy needles for withdrawal of blood samples.** (Pulse Picture Library/CMP Images/Phototake. Reproduced by Permission.)

### KEY TERMS

**Finger stick**—A technique for collecting a very small amount of blood from the fingertip area.

**Hemochromatosis**—A genetic disorder known as iron overload disease. Untreated hemochromatosis may cause osteoporosis, arthritis, cirrhosis, heart disease, or diabetes.

**Thrombocytosis**—A vascular condition characterized by high blood platelet counts.

**Tourniquet**—Any device that is used to compress a blood vessel to stop bleeding or as part of collecting a blood sample. Phlebotomists usually use an elastic band as a tourniquet.

into the vein and releases the elastic band. The appropriate amount of blood is drawn and the needle is withdrawn from the vein. The patient's pulse and blood pressure may be monitored during the procedure.

For some tests requiring very small amounts of blood for analysis, the technician uses a finger stick. A lance, or small needle, makes a small cut in the surface of the fingertip, and a small amount of blood is collected in a narrow glass tube. The fingertip may be squeezed to get additional blood to surface.

The amount of blood drawn depends on the purpose of the phlebotomy. Blood donors usually contribute a unit of blood (500 mL) in a session. The volume of blood needed for laboratory analysis varies widely with the type of test being conducted. Typically one or several small (5–10 mL) tubes are drawn. Therapeutic phlebotomy removes a larger amount of blood than donation and blood analysis require. Phlebotomy for treatment of hemochromatosis typically involves removing a unit of blood—250 mg of iron—once a week. Phlebotomy sessions are required until iron levels return to a consistently normal level, which may take several months to several years. Phlebotomy for polycythemia vera removes enough blood to keep the patient's hematocrit (proportion of red blood cells) below 45%. The frequency and duration of sessions depends on the patient's individual needs.

### Diagnosis/Preparation

Patients having their blood drawn for analysis may be asked to discontinue medications or to avoid food (to fast) for a period of time before the blood test. Patients donating blood will be asked for a brief medical history, have their blood pressure taken, and have their hematocrit checked with a finger stick test prior to donation.

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

Phlebotomy is usually performed by a phlebotomy technician. Arterial collection may be performed by a physician. Collection occurs in the hospital or outpatient clinic.

### Aftercare

After blood is drawn and the needle is removed, pressure is placed on the puncture site with a cotton ball to stop bleeding, and a bandage is applied. It is not uncommon for a patient to feel dizzy or nauseated during or after phlebotomy. The patient may be encouraged to rest for a short period once the procedure is completed. Patients are also instructed to drink plenty of fluids and eat regularly over the next 24 hours to replace lost blood volume. Patients who experience swelling of the puncture site or continued bleeding after phlebotomy should seek immediate medical treatment.

### Risks

Most patients will have a small bruise or mild soreness at the puncture site for several days. Therapeutic phlebotomy may cause thrombocytosis and chronic iron deficiency (anemia) in some patients. As with any invasive procedure, infection is also a risk. This risk is minimized by the use of prepackaged sterilized equipment and careful attention to proper technique. There is no risk of HIV infection from phlebotomy, since all needles are disposed of after a single use. Arterial blood collection carries a higher risk than venous collection, and is performed by a physician or other specially trained professional. Patients who are anemic or have a history of cardiovascular disease may not be good candidates for phlebotomy.

### Normal results

Normal results include obtaining the needed amount of blood with the minimum of discomfort to the patient.

### Morbidity and mortality rates

Properly performed, phlebotomy does not carry the risk of mortality. It may cause temporary pain and bleeding, but these are usually easily managed.

### Alternatives

Phlebotomy is a necessary medical procedure, and is required for a wide variety of other procedures.

## QUESTIONS TO ASK THE DOCTOR

- How many tubes of blood will you withdraw?

## Photocoagulation therapy

### Definition

Photocoagulation therapy is a method of treating detachments (tears) of the retina (the layer of light-sensitive cells at the back of the eye) with an argon laser. The high-intensity beam of light from the laser is converted into heat, which forces protein molecules in the affected tissue to condense and seal the tear.

### Purpose

The purpose of photocoagulation therapy is to reattach a torn or detached portion of the retina and/or prevent further growth of abnormal blood vessels in the retina that can cause a detachment.

### Demographics

The incidence of RD in the United States is about 0.3%, or one in 15,000 people.

The most common risk factors associated with RD are extreme nearsightedness (5% risk); cataract removal without lens implantation (2%); and cataract removal with loss of the vitreous body during surgery (10%). It is estimated that 15% of people with RD in one eye will eventually develop it in the other eye.

Males account for 60% and females for 40% of patients with RD below the age of 45. Above age 45, there is no significant gender difference.

With regard to racial or ethnic background, the incidence of RD is higher among Jews in the United

## KEY TERMS

**Choroid**—The middle of the three tunicae or coats that surround the eyeball; the choroid lies between the retina and the sclera.

**Coats' disease**—A chronic and progressive disorder of the retina marked by exudative RD. It is named for George Coats (1876-1915), a British ophthalmologist. It occurs most frequently in preadolescent boys and young adults.

**Cornea**—The transparent front portion of the exterior cover of the eye.

**Cryopexy**—Reattachment of a detached retina by freezing the tissue behind the tear with nitrous oxide.

**Diabetic retinopathy**—Degeneration of the retina related to diabetes; both type 1 and type 2 diabetes can lead to diabetic retinopathy.

**Eales disease**—A disorder marked by recurrent hemorrhages into the retina and vitreous body. It occurs most often in males between the ages of 10 and 25.

**Exudative RD**—A type of retinal detachment caused by the accumulation of tissue fluid underneath the retina.

**Floaters**—Spots seen in front of the eyes, caused by clumping of the collagen fibers in the vitreous body.

**Laser**—A device that produces high-intensity, narrowly focused monochromatic light by exciting atoms and causing them to give off their energy in phase.

**Laser in situ keratomileusis (LASIK)**—A procedure in which the shape of the cornea is changed with an excimer laser in order to correct the patient's vision.

**Macula**—A small, yellowish depressed area on the retina that absorbs the shorter wave lengths of visible light and is responsible for fine detailed vision.

**Marfan's syndrome**—A hereditary disorder that affects the connective tissues of the body, the lens of the eye, and the cardiovascular system.

**Ophthalmology**—The branch of medicine that deals with the diagnosis and treatment of eye disorders.

**Optometrist**—A primary health care provider who examines eyes and diagnoses disorders of the eye as well as prescribing eyeglasses, contact lenses, and other vision aids.

**Pneumatic retinopexy**—Reattachment of a detached retina using an injected gas bubble to hold the retina against the back of the eye.

**Pupil**—The opening in the center of the iris of the eye that allows light to enter the eye.

**Retina**—The innermost of three layers of tissue surrounding the human eyeball. The retina surrounds the vitreous body and joins the optic nerve at the back of the eye.

**Retinal detachment (RD)**—A condition in which the inner layers of cells in the retina separate from the underlying pigmented layers of cells called the choroid.

**Retinopathy of prematurity (ROP)**—A disorder that occurs in premature infants in which blood vessels in the eye continue to grow in an abnormal pattern after delivery. It can lead to retinal detachment and blindness. ROP is also known as retrolental fibroplasia.

**Sclera**—The tough white outer tunica or coat of the eyeball.

**Tunica (plural, tunicae)**—The medical term for a membrane or piece of tissue that covers or lines a body part. The retina is the innermost of three tunicae that surround the eyeball.

**Vitrectomy**—Surgical removal of the vitreous body.

**Vitreous body**—The transparent gel that fills the inner portion of the eyeball between the lens and the retina. It is also called the vitreous humor or crystalline humor.

States than in the general population; the incidence of RD among African Americans is lower than average.

## Description

### *Structure of the human eye*

To fully understand how photocoagulation therapy works, it is helpful to have a basic picture of the structure of the human eye. The retina is the innermost tunica, or covering, of the posterior part of the eyeball. It is made of several layers of cells, one of which

contains the rod and cone cells that are sensitive to light. Behind the retina are the other two tunicae of the eye, the choroid and the sclera. The sclera is a tough white layer of tissue that covers the exterior of the eyeball. At the front of the eye, the sclera is continuous with a transparent area of tissue known as the cornea.

At the back of the eye, the retina is continuous with the optic nerve. The macula, which is a yellowish oval-shaped area that is the central point of vision, lies in the center of the retina. In front of the retina is the vitreous body, which is also known as the vitreous humor, or

simply the vitreous. The vitreous body is a clear gel that consists primarily of water and collagen fibers.

### *Types of retinal detachment (RD)*

**RHEGMATOGENOUS.** A rhegmatogenous RD is the most common of the three types of retinal detachment. The word rhegmatogenous comes from a Greek word that means “tear.” A rhegmatogenous RD typically occurs in older people. As the vitreous body in the center of the eyeball ages, it shrinks and pulls away from the retina. This separation is called a posterior vitreous detachment (PVD). A PVD is not the same thing as a retinal detachment, although it may slightly increase the risk of an RD. In places where the retina is still attached to the vitreous body, a small hole or tear can develop. Over time, fluid can seep into the area around the hole or tear and thus enlarge the area of detached tissue.

**TRACTION.** Traction RDs are most often found in adults with diabetic retinopathy or infants with retinopathy of prematurity (ROP). Diabetic retinopathy is a disorder that develops when the patient’s diabetes affects the small blood vessels in the eye. Although diabetic retinopathy is more severe in patients with type 1 diabetes (insulin-dependent), it can also occur in patients with type 2. Retinal detachment is most likely to occur in a subtype of the disorder known as proliferative diabetic retinopathy. The term proliferative refers to the abnormal growth of new blood vessels along the surface of the vitreous body. These new blood vessels can bleed into the vitreous body and form scar tissue that pulls on the retina. Eventually, the scar tissue can exert enough pulling force to cause a retinal detachment.

In ROP, a traction RD can develop because premature birth interrupts the normal development of the blood vessels in the baby’s eyes. After the baby is born, some of these blood vessels grow along the retina, bleed into the vitreous body, and form scar tissue similar to that found in diabetic retinopathy. Retinal detachment in ROP can be treated with photocoagulation.

**EXUDATIVE.** Exudative RDs occur when tissue fluid builds up in the space between the retina and the choroid underneath it. If enough fluid leaks into this space, it can push the retina away from the choroid and cause it to detach. Exudative RDs are associated with certain inflammatory disorders of the eye; tumors, including melanoma (cancer) of the choroid; and a congenital disorder known as Coats’ disease, which affects the growth of the blood vessels in the retina.

### *Risk factors for retinal detachment*

Retinal detachment is associated with a number of different factors and conditions, including:

- extreme nearsightedness
- genetic factors (retinal detachment tends to run in families)
- premature birth (the risk of ROP is highest in premature infants weighing less than 2.2 lb [1 kg] at birth)
- type 1 or type 2 diabetes
- cataract surgery
- sickle cell disease
- Coats’ disease
- Eales’ disease
- Marfan’s syndrome
- breast cancer or melanoma
- leukemia
- history of previous retinal detachment
- age (Retinal detachment is most common in people between the ages of 40 and 70.)
- traumatic injury to the eye
- laser in-situ keratomileusis surgery (LASIK, a procedure done to correct vision and eliminate the need for glasses or contact lenses)

Photocoagulation therapy for retinal detachment is usually performed with an argon laser. A laser is a device that produces high-intensity, narrowly focused monochromatic light by exciting atoms and causing them to give off their energy in phases. The word laser comes from “light amplification by stimulated emission of radiation.” An argon laser uses ionized argon to generate its light, which is in the blue-green portion of the visible light spectrum.

In a laser photocoagulation treatment, the patient is asked to sit in front of the instrument. After applying anesthetic eye drops, the ophthalmologist places a contact lens on the patient’s eye and focuses the laser beam through it. He or she operates the laser by foot. The patient may see a brief burst of blue-green light. When the laser beam reaches the retina at the back of the eye, its light is absorbed by the pigment in the cells and converted to heat, which seals the edge of the retinal detachment against the underlying choroid. The procedure is short, taking about 10–30 minutes.

## **Diagnosis/Preparation**

### *Diagnosis*

The diagnosis of retinal detachment requires direct examination of the eye as well as taking the patient’s medical history. The diagnosis may be made in some cases by an optometrist, who is a health professional qualified to examine the eye for diseases and disorders as well as taking measurements for corrective lenses. If the symptoms of RD appear suddenly,

however, the patient is more likely to be diagnosed by an ophthalmologist, who is a physician specializing in treating disorders of the eye.

**PATIENT HISTORY.** Retinal detachment is not usually painful, and the patient's eye will look normal from the outside. In almost all cases, a patient with RD consults a doctor because he or she is having one or more of the following visual disturbances:

- blurring of vision that is not helped by blinking the eye
- a gray or black curtain or shade coming across the field of vision from one direction
- floaters, which appear as moving black spots in front of the eye (The sudden appearance of a large group, or "shower," of floaters is a serious symptom of RD.)
- flashes of light
- objects appearing wavy or distorted in shape
- blind spot in the visual field

The visual symptoms of retinal detachment may develop either gradually or suddenly. In a very small number of cases, a sudden retinal detachment may cause complete loss of vision in the affected eye.

Patients who have gone to a primary care physician or emergency room for these visual symptoms are referred to an ophthalmologist. Many ophthalmologists will give patients a piece of paper with a circle on it and ask them to draw what they are seeing on the circle in the area corresponding to the part of their visual field that is affected. In some cases, the location of the spots, light flashes, or shadows that a patient sees is a clue to the part of the retina that is detached.

The ophthalmologist will take a patient history, asking about a family history of eye disorders; previous diseases or disorders of the eye; other diseases or disorders that the patient may have, particularly diabetes or sickle cell disease; and a history of head trauma, direct blows to the eye, or surgical removal of a foreign body from the eye. If the patient suffered a head or eye injury within the past six months, the ophthalmologist will ask whether the visual disturbances started at the time of the injury or several months later.

**EYE EXAMINATION.** After taking the history, the ophthalmologist will examine the eye itself. This examination has several parts, including:

- A test of visual clarity or sharpness. This test is the same one used by an optometrist when fitting a patient for glasses or contact lenses.
- An external check for bleeding or any other signs of trauma to the eye.

- A test that measures the response of the pupil of the eye to changes in light intensity. One sign of RD is a difference in the pupillary reaction between the affected eye and the normal one. The pupil will not contract as far as it normally does when the doctor shines a light into the affected eye.
- A test that measures the amount of fluid pressure inside each eyeball. In RD, the affected eye typically has a lower pressure measurement than the other eye.
- Examination of the eye with a slit lamp, which is an instrument with a high-intensity light source that can be focused as a thin sliver of light. The examiner uses the slit lamp together with a binocular ophthalmoscope (an instrument that looks like a microscope with two eyepieces) in order to check first the front and then the back of the eye for any abnormalities. To check the front part, the doctor will touch the side of the eye with a strip of paper containing an orange dye. The dye stains the film of tear fluid on the outer surface of the eye, making it easier to see the structures in the front of the eye. Patients with RD usually have normal results for this part of the slit-lamp examination. In the second part, the doctor puts some drops in the patient's eye to make the pupil dilate. This procedure allows him or her to see the structures in the back of the eye. If the patient has RD, the doctor may see the retina lifted upward or forward, possibly moving back and forth. The retina will have a grayish color with darker blood vessels visible. It may have a pitted surface resembling an orange peel, and there may also be a line visible at the edge of the detachment.

**LABORATORY AND IMAGING STUDIES.** Today, there are no laboratory tests for retinal detachment. **Ultrasound**, however, can be used to diagnose retinal detachment if the doctor cannot see the retina with a slit lamp because of cataracts or blood seeping into the vitreous body. If the RD is exudative, ultrasound can be used to detect a tumor or hemorrhage underneath the retina.

### *Preparation*

Treatment of RD follows as soon as possible after the diagnosis; however, an immediate procedure is not usually necessary since the time frame for treatment of a detached retina is several hours rather than only a few minutes.

If the patient has suffered a traumatic injury to the eye, the eye may be covered with a protective shield prior to treatment.

Preparation for photocoagulation therapy consists of eye drops that dilate the pupil of the eye and

numb the eye itself. The laser treatment is painless, although some patients require additional anesthetic for sensitivity to the laser light.

### Aftercare

Patients who have had photocoagulation therapy for retinal detachment are asked to have a friend or family member drive them home. The reason for this precaution is that the eye medication used to dilate the pupil of the patient's eye before the procedure takes several hours to wear off. During this period, the eye is unusually sensitive to light. The patient can go to work the next day with no restrictions on activity.

### Risks

The most common risks of laser photocoagulation therapy are mild discomfort at the beginning of the procedure and the possibility that a second laser treatment will be needed to reattach the retina securely.

### Normal results

Over 90% of retinal detachments can be repaired with prompt treatment, although sometimes a second procedure is needed. About 40% of patients treated for retinal detachment will have good vision within six months of surgery. The results are less favorable if the retina has been detached for a long time or if there is a large growth of fibrous tissue that has caused a traction detachment. These patients, however, will still have some degree of reading or traveling vision after the retina has been reattached. In a very small minority of patients, the surgeon cannot reattach the retina because of extensive growths of fibrous scar tissue on it.

### Morbidity and mortality rates

The mortality rate for laser photocoagulation treatment of retinal detachment is extremely low; morbidity depends to a large extent on the cause of the RD. A study done in 2001 reported that laser therapy for rhegmatogenous RDs is as effective as pneumatic retinopexy or **scleral buckling**, but has the advantage of fewer complications after the procedure. In the treatment of ROP, laser photocoagulation has been found to be more effective than cryopexy in reducing the infant's risk of nearsightedness in later life.

### Alternatives

Alternatives to laser photocoagulation as a treatment for RD depend on the location and size of the retinal detachment. Photocoagulation treatment works best on small tears in the retina. One alternative

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

Laser treatment of retinal detachment is performed by an ophthalmologist, who has specialized in the medical and surgical treatment of eye disorders. Ophthalmology is one of 24 specialties recognized by the American Board of Medical Specialties.

Photocoagulation therapy for retinal detachment is done as an outpatient procedure, either in the ophthalmologist's office or in an ambulatory surgery center.

for the treatment of small areas of detachment is cryopexy, which is performed as an outpatient procedure under **local anesthesia**. In cryopexy, the ophthalmologist uses nitrous oxide to freeze the tissue underneath the retinal tear. This procedure leads to the formation of scar tissue that seals the edges of the tear in place.

Pneumatic retinopexy is a procedure that can be used if the RD is located in the upper part of the eye. After numbing the patient's eye with a local anesthetic, the ophthalmologist injects a small bubble of gas into the vitreous body. The gas bubble rises and presses the torn part of the retina back against the underlying choroid. The bubble is slowly absorbed over the next two weeks. The ophthalmologist then uses either photocoagulation or cryopexy to complete the reattachment of the retina.

If the RD is large, the doctor may decide to perform a scleral buckle treatment or a vitrectomy. These procedures are more invasive than laser photocoagulation or cryopexy; however, they are still usually done as outpatient procedures. In a scleral buckle procedure, the doctor attaches a tiny silicon band to the sclera. The buckle, which remains in the eye permanently, puts pressure on the retina to hold it in place.

In a vitrectomy, the ophthalmologist removes the vitreous body and replaces it with air or a saline solution that puts pressure on the retina to hold it in place. Vitrectomies are usually performed if there is a very large tear in the retina; if the macula is involved; or if blood that has leaked into the vitreous body is interfering with diagnosis or treatment.

## QUESTIONS TO ASK THE DOCTOR

- What are my chances of having normal vision after the laser therapy?
- What is the likelihood of my needing another laser treatment?
- Am I likely to develop retinal detachment in my other eye?
- How often should I schedule preventive eye examinations from now on?

## Photorefractive keratectomy (PRK)

### Definition

Photorefractive keratectomy (PRK) is a noninvasive refractive surgery in which the surgeon uses an excimer laser to reshape the cornea of the eye by removing the epithelium, the gel-like outer layer of the cornea.

### Purpose

PRK, one of the first (and once the most popular) refractive surgeries, eliminates or reduces moderate nearsightedness (myopia), hyperopia (farsightedness), and astigmatism; it is most commonly used to treat myopia. Successfully treated PRK patients no longer require corrective lenses, and those who do still require correction, require much less.

PRK is an elective, **outpatient surgery**, and people choose the treatment for different reasons. Some simply no longer want to wear eyeglasses for cosmetic reasons. Sports enthusiasts may find eyeglasses or contact lenses troublesome during physical activities. Others may experience pain or dryness while wearing contact lenses, or have corneal ulcers that make wearing contact lenses painful. Firefighters and police officers may have trouble seeing in emergency situations when their contact lenses get dry or their eyeglasses fog up.

### Demographics

There is no such thing as a typical PRK patient. Because it is an **elective surgery**, patients come from every age group and income bracket. PRK candidates, however, must be 18 or older; have myopia, hyperopia, or astigmatism; and have had stable vision for at least two years. While PRK is experiencing a slight resurgence in popularity, it lags behind the newer and less painful **laser in-situ keratomileusis (LASIK)**. The American Academy of Ophthalmology (AAO) estimates that 95% of all refractive surgeries are **LASIK**.

## KEY TERMS

**Ablation**—The vaporization of eye tissue.

**Astigmatism**—Asymmetric vision defects due to irregularities in the cornea.

**Cornea**—The clear, curved tissue layer in front of the eye. It lies in front of the colored part of the eye (iris) and the black hole in the center of the iris (pupil).

**Corneal topography**—Mapping the cornea's surface with a specialized computer that illustrates corneal elevations.

**Dry eye**—Corneal dryness due to insufficient tear production.

**Enhancement**—A secondary refractive procedure performed in an attempt to achieve better visual acuity.

**Excimer laser**—An instrument that is used to vaporize tissue with a cold, coherent beam of light with a single wavelength in the ultraviolet range.

**Hyperopia**—The inability to see near objects as clearly as distant objects, and the need for accommodation to see objects clearly.

**Myopia**—A vision problem in which distant objects appear blurry. People who are myopic or nearsighted can usually see near objects clearly, but not far objects.

**Presbyopia**—A condition affecting people over the age of 40 in which the focusing of near objects fails to work because of age-related hardening of the lens of the eye.

The first PRK patients are sometimes referred to as “early adopters.” These are people who are always interested in the latest technology and have the financial resources to take advantage of it. In the mid-1990s when PRK was first approved, patients were in their early 30s to mid-40s and financially stable. Prices have now stabilized at about \$1,800 per eye for PRK.

While it has lost favor with the general public, PRK is the choice of the United States military. Military doctors prefer PRK over LASIK because the latter involves cutting a flap that doctors fear may loosen and become unhinged during combat.

### Description

PRK was first performed in the 1980s and widely used in Europe and Canada in the early 1990s, but was not approved in the United States until 1995. PRK

was the most popular refractive procedure until the creation of LASIK, which has a much shorter recovery time. PRK is still the preferred option for patients with thin corneas, corneal dystrophies, corneal scars, or recurrent corneal erosion.

PRK takes about 10 minutes to perform. Immediately before the procedure, the ophthalmologist may request corneal topography (a corneal map) to compare with previous maps to ensure the treatment plan is still correct. Ophthalmic personnel will perform a refraction to make sure the refractive correction the surgeon will program into the excimer laser is correct.

Patients may be given a sedative such as Valium to relax them before the surgery. Anesthetic drops will be applied to numb the eye and prevent pain during the procedure.

After the eye drops are inserted, the surgeon prepares the treated eye for surgery. If both eyes are being treated on the same day, the non-treated eye is patched. The surgeon inserts a speculum in the first eye to be treated to hold the eyelids apart and prevent movement. The patient stares at the blinking light of a laser microscope and must fixate his or her gaze on that light. The patient must remain still.

The surgeon double-checks the laser settings to make sure they are programmed correctly for the refractive error. With everything in place, the eye surgeon removes the surface corneal cells (epithelium) with a sponge, mechanical blade, or the excimer laser. With the epithelium completely removed, the surgeon will begin reshaping, or ablating, the cornea. This takes 15–45 seconds, and varies for refractive error; the stronger the error, the longer the ablation. Patients may worry that moving could cause irreversible eye damage, but they should know that, at the slightest movement, the doctor immediately stops the laser. When the ablation is completed, the surgeon places a bandage contact lens on the treated eye to protect it and allow the healing process to take place; it also eases some of the pain of the exposed cornea. The surgeon will also dispense anti-inflammatory and antibiotic eye drops to stop infection and reduce pain.

### Diagnosis/Preparation

Patients should have a complete eye evaluation and medical history taken before surgery. Soft contact lens wearers should stop wearing their lenses at least one week before the initial exam. Gas-permeable lens wearers should not wear their lenses from three weeks to a month before the exam. Contact lens wear alters the cornea's shape, which should be allowed to return to its natural shape before the exam.

Patients should also disclose current medications. Allergy medications and birth control pills have been known to cause haze after surgery. Physicians will want to examine the potential risks involved with these medications.

Patients who have these conditions/history should not have the procedure, including:

- pregnant women or women who are breastfeeding
- patients with very small or very large refractive errors
- patients with scarred corneas or macular disease
- people with autoimmune diseases
- diabetics
- glaucoma patients
- patients with persistent blepharitis

Physicians will perform a baseline eye evaluation, including a manifest and cycloplegic refraction, measurement of intraocular pressure (to determine if the patient has glaucoma), slit-lamp biomicroscopy, tear film evaluation, corneal topography, evaluation of corneal thickness, dilated fundus examination, and measurement of scotopic pupil size.

If the patient is an appropriate candidate, he or she must sign an **informed consent** form that states he or she is aware of possible complications and outcomes of the procedure.

#### *Presurgery preparations*

The patient is advised to discontinue contact lens wear immediately and refrain from using creams, lotions, makeup, or perfume for at least two days before surgery. Patients may also be asked to scrub their eyelashes for a period of time to remove any debris.

#### **Aftercare**

Patients usually have follow-up appointments at 24 hours, four days, one week, one month, three months, six months, and then annually following PRK. More frequent visits may be necessary, if there are complications.

Patients should refrain from strenuous activity for at least one month after surgery. Creams, lotions, and makeup must also be avoided for at least two weeks.

The bandage contact lens is removed by the surgeon usually after four days (during the second visit). Patients must be diligent in using antibiotic drops and steroid drops. Because the epithelium is completely removed, there is a greater chance of infection and pain; the eye drops are needed to minimize these possible complications. The eye drops must be used for at

least four months for some patients. The slow healing process is imperative to keeping the desired correction.

PRK has a long recovery rate, which is why LASIK gained popularity so quickly. Unlike LASIK, in which patients notice improved vision immediately and are back to normal routines the next day, PRK patients are advised to rest for at least two days. PRK patients also experience moderate pain the first few days of recovery, and may need pain relievers such as Demerol to ease the pain. Vision also fluctuates the first few weeks of recovery as the epithelium grows back. This can cause haze, and patients become concerned that the surgery was unsuccessful. PRK patients need to be aware that vision can fluctuate for as long as up to six months after surgery. Incorrect use of eye drops can cause regression.

#### **Risks**

PRK patients may experience glare, vision fluctuation, development of irregular astigmatism, vision distortion (even with corrective lenses), glaucoma, loss of best visual acuity, and, though extremely rare, total vision loss.

A more common side effect is long-term haze. Some patients who have aggressive healing processes can form corneal scars that can cause haze. With proper screening for this condition and with the use of eye drops, this risk can be lessened.

Complications associated with LASIK, such as photophobia, haloes, and dry eye, are not as common with PRK. However, The patient may be under-corrected or overcorrected, and enhancements might be needed to attain the best visual acuity.

#### **Normal results**

Most PRK patients achieve 20/40 vision, which means in most states they can legally drive a car without vision correction. Some patients will still need corrective lenses, but the lenses will not need to be as powerful.

There have been reports of regression after the PRK healing process is completed. Sometimes a patient will require an enhancement, and the surgeon must repeat the surgery. Patients should also be aware that with the onset of presbyopia after age 40, they will probably require vision correction for reading or close work.

#### **Morbidity and mortality rates**

Information about PRK mortality and morbidity is limited because the procedure is elective. Complications that can lead to more serious conditions, such as

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

An ophthalmologist performs PRK with the aid of ophthalmic technicians and nurses. The surgeon may have received specific refractive surgery training in medical school, but because it is a relatively new procedure, older surgeons may not have completed such training. Instead, these surgeons may have completed continuing medical education courses or may have had training provided by the laser companies.

Preparation and aftercare may be handled by an optometrist who works with the ophthalmologist on these cases. The optometrist usually establishes eligibility for PRK, and may also perform much of the follow-up, with the exception of the first post-PRK visit.

Hospitals are one setting for this surgery, but the most common location is an ambulatory surgery center or surgery suite. Surgeons at surgery centers owned by refractive surgery companies also perform PRK. These businesses hire support staff, optometrists and surgeons in a stand-alone surgery center or in a hospital.

infection, are treated with **topical antibiotics**. There is also a chance the patient could have a severe reaction to the **antibiotics** or steroids used in the healing process.

### Alternatives

Because these patients only have mild to moderate myopia, hyperopia, or astigmatism, they can choose from most refractive surgeries and non-surgical procedures.

#### *Surgical alternatives*

- **Laser in-situ keratomileusis (LASIK).** The most popular refractive surgery, it is similar to PRK, but differs in how it reshapes the cornea. Instead of completely removing tissue, LASIK leaves a “flap” of tissue that the surgeon moves back into place after ablation. LASIK is less painful with a shorter recovery time. However, there are more complications associated with LASIK.
- **Radial keratotomy (RK).** RK was the first widely used surgical correction for mild to moderate

## QUESTIONS TO ASK THE DOCTOR

- Why do you believe that PRK is the correct refractive surgery for me?
- How many PRK procedures have you performed?
- Is PRK your preferred procedure?
- How well will I see after the surgery?
- How many of your patients experience serious complications?
- Who will treat complications, if any, after the procedure?
- How long with the recovery process take? Do I need to limit my activities?

myopia. The surgeon alters the shape of the cornea without a laser. This is one of the oldest refractive procedures, and has proved successful on lower and moderate corrections.

- **Astigmatic keratotomy (AK).** AK is a variation of RK used to treat mild to moderate astigmatism. AK has proved successful if the errors are mild to moderate.

#### *Non-surgical alternatives*

Contact lenses and eyeglasses also can correct refractive errors. Improvements in contact lenses have made them easier to wear, and continuous-wear contact lenses, which a patient can sleep in for as long as 30 days, can provide a similar effect to PRK. A customized rigid gas-permeable contact lens is used for orthokeratology (Ortho-K), in which a patient wears the lens for a predetermined amount of time to reshape the cornea. After removing the lens, the patient’s vision is improved and remains improved until the cornea returns to its natural shape. At that time, the patient repeats the process.

## Physical examination

### Definition

A physical examination is an evaluation of the body and its functions using inspection, palpation (feeling with the hands), percussion (tapping with the fingers), and auscultation (listening). A complete health assessment also includes gathering information about a person's medical history and lifestyle, doing laboratory tests, and screening for disease.

### Purpose

The annual physical examination has been replaced by the periodic health examination. How often this is done depends on the patient's age, sex, and risk factors for disease. The United States Preventative Services Task Force (USPSTF) has developed guidelines for preventative health examinations that health care professionals widely follow. Organizations that promote detection and prevention of specific diseases, like the American Cancer Society, generally recommend more intensive or frequent examinations.

A comprehensive physical examination provides an opportunity for the healthcare professional to obtain baseline information about the patient for future use, and to establish a relationship before problems happen. It provides an opportunity to answer questions and teach good health practices. Detecting a problem in its early stages can have good long-term results.

### Precautions

The patient should be comfortable and treated with respect throughout the examination. As the examination proceeds, the examiner should explain what he or she is doing and share any relevant findings.

### Description

A complete physical examination usually starts at the head and proceeds all the way to the toes. However, the exact procedure will vary according to the needs of the patient and the preferences of the examiner. An average examination takes about 30 minutes. The cost of the examination will depend on the charge for the professional's time and any tests that are done. Most health plans cover routine physical examinations including some tests.

#### *The examination*

First, the examiner will observe the patient's appearance, general health, and behavior, along with measuring height and weight. The vital signs—including pulse, breathing rate, **body temperature**, and blood pressure—are recorded.

With the patient sitting up, the following systems are reviewed:

- Skin. The exposed areas of the skin are observed; the size and shape of any lesions are noted.
- Head. The hair, scalp, skull, and face are examined.
- Eyes. The external structures are observed. The internal structures can be observed using an ophthalmoscope (a lighted instrument) in a darkened room.
- Ears. The external structures are inspected. A lighted instrument called an otoscope may be used to inspect internal structures.
- Nose and sinuses. The external nose is examined. The nasal mucosa and internal structures can be observed with the use of a penlight and a nasal speculum.
- Mouth and pharynx. The lips, gums, teeth, roof of the mouth, tongue, and pharynx are inspected.
- Neck. The lymph nodes on both sides of the neck and the thyroid gland are palpated (examined by feeling with the fingers).
- Back. The spine and muscles of the back are palpated and checked for tenderness. The upper back, where the lungs are located, is palpated on the right and left sides and a stethoscope is used to listen for breath sounds.

- **Breasts and armpits.** A woman's breasts are inspected with the arms relaxed and then raised. In both men and women, the lymph nodes in the armpits are felt with the examiner's hands. While the patient is still sitting, movement of the joints in the hands, arms, shoulders, neck, and jaw can be checked.

Then while the patient is lying down on the examining table, the examination includes:

- **Breasts.** The breasts are palpated and inspected for lumps.
- **Front of chest and lungs.** The area is inspected with the fingers, using palpation and percussion. A stethoscope is used to listen to the internal breath sounds.

The head should be slightly raised for:

- **Heart.** A stethoscope is used to listen to the heart's rate and rhythm. The blood vessels in the neck are observed and palpated.

The patient should lie flat for:

- **Abdomen.** Light and deep palpation is used on the abdomen to feel the outlines of internal organs including the liver, spleen, kidneys, and aorta, a large blood vessel.
- **Rectum and anus.** With the patient lying on the left side, the outside areas are observed. An internal digital examination (using a finger), is usually done if the patient is over 40 years old. In men, the prostate gland is also palpated.
- **Reproductive organs.** The external sex organs are inspected and the area is examined for hernias. In men, the scrotum is palpated. In women, a pelvic examination is done using a speculum and a Papanicolaou test (Pap test) may be taken.
- **Legs.** With the patient lying flat, the legs are inspected for swelling, and pulses in the knee, thigh, and foot area are found. The groin area is palpated for the presence of lymph nodes. The joints and muscles are observed.
- **Musculoskeletal system.** With the patient standing, the straightness of the spine and the alignment of the legs and feet is noted.
- **Blood vessels.** The presence of any abnormally enlarged veins (varicose), usually in the legs, is noted.

In addition to evaluating the patient's alertness and mental ability during the initial conversation, additional inspection of the nervous system may be indicated:

- **Neurologic screen.** The patient's ability to take a few steps, hop, and do deep knee bends is observed. The strength of the hand grip is felt. With the patient sitting down, the reflexes in the knees and feet can be tested with a small hammer. The sense of touch in

the hands and feet can be evaluated by testing reaction to pain and vibration.

- Sometimes additional time is spent examining the 12 nerves in the head (cranial) that are connected directly to the brain. They control the sense of smell, strength of muscles in the head, reflexes in the eye, facial movements, gag reflex, and muscles in the jaw. General muscle tone and coordination, and the reaction of the abdominal area to stimulants like pain, temperature, and touch would also be evaluated.

## Preparation

Before visiting the health care professional, the patient should write down important facts and dates about his or her own medical history, as well as those of family members. He or she should have a list of all medications with their doses or bring the actual bottles of medicine along. If there are specific concerns about anything, writing them down is a good idea.

Before the physical examination begins, the bladder should be emptied and a urine specimen can be collected in a small container. For some blood tests, the patient may be told ahead of time not to eat or drink after midnight.

The patient usually removes all clothing and puts on a loose-fitting hospital gown. An additional sheet is provided to keep the patient covered and comfortable during the examination.

## Aftercare

Once the physical examination has been completed, the patient and the examiner should review what laboratory tests have been ordered and how the results will be shared with the patient. The medical professional should discuss any recommendations for treatment and follow-up visits. Special instructions should be put in writing. This is also an opportunity for the patient to ask any remaining questions about his or her own health concerns.

## Risks

Other than discovering an unknown condition or health problem, which is the reason for performing a physical examination, there are no risks associated with the procedure.

## Normal results

Normal results of a physical examination correspond to the healthy appearance and normal functioning of the body. For example, appropriate reflexes will be

## KEY TERMS

**Auscultation**—The process of listening to sounds that are produced in the body. Direct auscultation uses the ear alone, such as when listening to the grating of a moving joint. Indirect auscultation involves the use of a stethoscope to amplify the sounds from within the body, like a heartbeat.

**Hernia**—The bulging of an organ, or part of an organ, through the tissues normally containing it; also called a rupture.

**Inspection**—The visual examination of the body using the eyes and a lighted instrument if needed. The sense of smell may also be used.

**Ophthalmoscope**—Lighted device for studying the interior of the eyeball.

**Otoscope**—An instrument with a light for examining the internal ear.

**Palpation**—The examination of the body using the sense of touch. There are two types: light and deep.

**Percussion**—An assessment method in which the surface of the body is struck with the fingertips to obtain sounds that can be heard or vibrations that can be felt. It can determine the position, size, and consistency of an internal organ. It is done over the chest to determine the presence of normal air content in the lungs, and over the abdomen to evaluate air in the loops of the intestine.

**Reflex**—An automatic response to a stimulus.

**Speculum**—An instrument for enlarging the opening of any canal or cavity in order to facilitate inspection of its interior.

**Stethoscope**—A Y-shaped instrument that amplifies body sounds such as heartbeat, breathing, and air in the intestine. Used in auscultation.

**Varicose veins**—The permanent enlargement and twisting of veins, usually in the legs. They are most often seen in people with occupations requiring long periods of standing, and in pregnant women.

present, no suspicious lumps or lesions will be found, and **vital signs** will be normal.

## Abnormal results

Abnormal results of a physical examination include any findings that indicated the presence of a disorder, disease, or underlying condition. For example, the presence of lumps or lesions, fever, muscle weakness or lack

of tone, poor reflex response, heart arrhythmia, or swelling of lymph nodes will point to a possible health problem.

## Planning a hospital stay

### Definition

Planning a hospital stay includes determining what hospitals or facilities are covered by the patient's insurance plan, evaluating the credentials of the health care providers and the hospital, gathering information about the hospital, including services offered, scheduling the hospital stay, completing pre-admission testing, receiving and following all of the appropriate pre-admission instructions, registering at the hospital upon arrival, and completing an **informed consent** form.

### Purpose

Patients are admitted to the hospital for a variety of reasons, including scheduled tests, procedures, or surgeries, emergency medical treatment, administration of medication, or to stabilize or monitor an existing medical condition.

Planning a hospital stay helps the patient understand what to expect before **admission to the hospital** and ensures the patient is physically and psychologically ready.

### Description

If the hospital stay was planned, some of the steps involved in preparing for the hospital stay will take place beginning one to two weeks before the patient is admitted to the hospital. Many of these steps will not apply if the hospital stay was unexpected or was the result of an emergency.

### Determining insurance coverage

Although there are many types of hospitals available to meet the needs of different patients, the patient's choice of hospital may be limited by his or her insurance plan. The patient should find out if the selected hospital is approved by his or her plan. If the patient receives care from a facility that is not approved by the health care plan, the patient may be responsible for paying for most or all of the medical expenses related to the hospital stay.

Managed care insurance plans often require pre-certification before any hospital stay, except for emergency hospital admissions. Usually, the patient's doctor has to authorize the hospital stay, and some types of care provided in the hospital may require insurance clearance.

If the patient has **Medicare** insurance (for patients over age 65), a semiprivate room, meals, general nursing care, and other **hospital services** and supplies are covered services. Those services not covered by Medicare include private duty nursing, a private room (unless medically necessary), and television and telephone fees.

The patient may desire to seek a **second opinion** to confirm the doctor's treatment recommendations. The patient should check with his or her insurance provider to determine if the second opinion consultation is covered.

**FOR PATIENTS WITHOUT INSURANCE COVERAGE.** For patients who do not have insurance coverage, other payment options and sources of financial aid can be discussed. The patient should ask to speak with the hospital's financial counselor for more information.

### Evaluating credentials

The patient should find out if the physicians who will provide care in the hospital are board certified. Even though board certification is not required for an individual physician to practice medicine, most hospitals require that a certain percentage of their staff be board certified. There are 24 certifying boards recognized by the American Board of Member Specialties (ABMS) and the American Medical Association (AMA). Most of the ABMS boards issue time-limited certificates, valid for six to 10 years. This requires physicians to become re-certified to maintain their board certification—a process that includes a credential review, continuing education in the specialty, and additional examinations.

## KEY TERMS

**Anesthesiologist**—A specially trained physician who administers anesthesia.

**Case manager**—A health care professional who can provide assistance with a patient's needs beyond the hospital.

**Catheter**—A small, flexible tube used to deliver fluids or medications or used to drain fluid or urine from the body.

**Clinical nurse specialists**—Nurses with advanced training as well as a master's degree.

**Discharge planner**—A health care professional who helps patients arrange for health and home care needs after they go home from the hospital.

**Electrocardiogram (ECG, EKG)**—A test that records the electrical activity of the heart using small electrode patches attached to the skin on the chest.

**General anesthesia**—Anesthesia that makes the patient unconscious and not feel pain.

**Guided imagery**—A form of focused relaxation that coaches the patient to visualize calm, peaceful images.

**Infectious disease team**—A team of physicians who help control the hospital environment to protect patients against harmful sources of infection.

**Informed consent**—An educational process between health care providers and patients intended to instruct the patient about the nature and purpose of the procedure or treatment, the risks and benefits of the procedure, and alternatives, including the option of not proceeding with the test or treatment.

**Inpatient surgery**—Surgery that requires an overnight stay of one or more days in the hospital.

**Local anesthesia**—Anesthesia that numbs a localized area of the body.

**NPO**—A term that means "nothing by mouth." NPO refers to the time after which the patient is not allowed to eat or drink prior to a procedure or treatment.

**Nurse manager**—The nurse responsible for managing the nursing care on the nursing unit and also supervises all of the other personnel who work on the nursing unit.

**Nursing unit**—The floor or section of the hospital where patient rooms are located.

**Outpatient surgery**—Also called same-day or ambulatory surgery.

**Pharmacologist**—Medication specialist who checks patients' blood levels to monitor their response to immunosuppressive medications.

**Regional anesthesia**—Anesthesia that does not make the patient unconscious; it works by blocking sensation in a region of the body.

**Registered nurses**—Specially trained nurses who provide care during the patient's hospital stay. Registered nurses provide medical care, medications, and education, as well as assess the patient's condition.

**Social worker**—A health care provider who can provide support to patients and families, including assistance with a patient's psychosocial adjustment needs and referrals for community support.

A physician's membership in professional societies is also an important consideration. Professional societies provide an independent forum for medical specialists to discuss issues of mutual interest and concern. They provide a place for doctors to discuss the latest practices and technologies, and to learn from each others' experiences of cases that went well or poorly. Examples of professional societies include the Society of Thoracic Surgeons (STS) and the American College of Physicians–American Society of Internal Medicine (ACP-ASIM).

To find information about a physician's qualifications, the patient can call a state or county medical association for assistance. A reference book is also available, *The Official ABMS Directory of Board-Certified Medical Specialists*, which lists all physicians

who are certified by approved boards. This publication also contains brief information about each physician's medical education and training. The directory can be found in many hospital and university libraries, and in some local libraries.

### *Evaluating the health care team*

Selecting a hospital that has a multi-disciplinary team of specialists is important. The medical team should include surgeons (as applicable), physicians who specialize in the patient's medical condition (such as cardiologists for heart disease and pulmonologists for lung disease), infectious disease specialists, pharmacologists, and advanced care registered nurses. Other medical team members may include fellows, residents, interns, clinical coordinators, physical therapists, occupational therapists,

respiratory therapists, registered dietitians, social workers, and financial counselors.

### *Evaluating the hospital*

The patient should find out if the hospital has been accredited by the Joint Commission on Accreditation of Healthcare Organizations, a professionally sponsored program that stimulates a high quality of patient care in health care facilities. Joint Commission accreditation means the hospital voluntarily sought accreditation and met national health and safety standards.

Here are some questions to consider when evaluating a hospital:

- Does the hospital offer treatment for the patient's specific condition? How experienced is the hospital staff in treating that condition?
- What is the hospital's success record in providing the specific medical treatment or procedure the patient needs?
- Does the hospital have experience treating other patients the same age as the potential patient?
- Does the hospital explain the patient's rights and responsibilities?
- Does the hospital have a written description of its services and fees?
- How much does the patient's type of treatment cost at the hospital?
- Is financial help available?
- Who will be responsible for the patient's specific care plan while he or she is in the hospital?
- If the hospital is far from the patient's home; will accommodations be provided for caregivers?
- What type of services are available during the patient's hospital stay?
- Will a discharge plan be developed before the patient goes home from the hospital?
- Does the hospital provide training to help the patient care for his or her condition at home?

### *Hospital services*

Usually, the patient receives information about the hospital from the admitting office when the hospital stay is scheduled. This information should include directions to the hospital, parking information, lodging information if the patient is from out of town, types of rooms, and services offered.

Hospital services offered may include:

- Ethics consultation: Bioethics professionals are available at most hospitals to provide advice or help the

patient identify, analyze, and resolve ethical issues that may arise during the patient's care at the hospital.

- Barber or beautician: These services may incur a fee, in addition to the fees of the patient's hospital stay.
- Complementary techniques such as guided imagery and relaxation tapes, massage therapy, or aromatherapy (to reduce a patient's stress and anxiety).
- Home care: If home health services will be needed after the patient is discharged, they can be arranged by the social worker or nursing staff.
- Interpreter: An interpreter or other special services may be available to assist patients and family members who do not speak the language or are from out of the country.
- Nutrition therapy: Registered dietitians are available to provide comprehensive nutrition assessment, counseling, and education.
- Ombudsman: Health care personnel available to address concerns and problems about medical services that cannot be resolved by reporting these concerns to the nursing staff.
- Pastoral care: Clergy members are available at most hospitals to provide religious support and services to meet patients' spiritual needs. Many hospitals also have a small chapel that provides a quiet retreat for patients and family members of all religious backgrounds and faiths.
- Patient education: A variety of services are available to teach patients about their medical condition or to help them prepare for their scheduled tests or procedures. Patient education may include one-on-one instruction from a health care provider, educational sessions in a group setting, or self-guided learning videos or modules. Informative and instructional handouts are usually provided to explain specific medications, tests, or procedures.
- Pediatric services: Many hospitals have dedicated services and programs available to help children, teenagers, and their parents feel better prepared to cope more effectively with hospital stays, surgery, procedures, and other health-related events.
- Social work: Social workers are available to help patients manage the changes that may occur as a result of the patient's hospitalization. Social workers provide referrals to community resources and can help the family make arrangements for care in the home as necessary after the patient is discharged from the hospital.

### *Patient rights and responsibilities*

All hospitals have a list of **patient rights** and responsibilities, established by the American Hospital

Association. These rights and responsibilities are usually published and posted throughout the hospital. By law, all patients have certain rights. Some patient rights include the right to:

- considerate and respectful care
- complete information about diagnosis, treatment, and expected recovery in terms the patient can understand
- knowledge of the name and function of any health care professional providing care
- informed consent
- the right to refuse treatment to the extent permitted by law and be informed of the medical consequences of refusing treatment

Each patient should obtain a list of his or her rights and responsibilities prior to a hospital admission.

### *Hospital environment*

Most hospital rooms have a bed, bedside table, chair, telephone, television, and bathroom. Some hospitals charge a fee for use of the telephone or television; patients should be notified of these charges prior to their hospital admission. Each patient area has a call signal button so the patient can notify the nursing staff if help is needed. Most hospital rooms are doubles that are shared by two patients. In many cases a private room can be specifically requested in one is available. Some hospitals also have wards in which four or more patients stay in one room. Three nutritionally balanced meals are provided to the patient daily during a hospital stay; daily menus are usually provided for patients to select their food choices, as applicable. (Some patients have dietary restrictions so their food choices may be limited.)

### *Hospital caregivers*

Sometimes, the patient's personal or family physician is not the attending physician who is in charge of the patient's overall care and treatment in the hospital. The attending physician may be a doctor on the hospital staff or a specialist. Fellows, residents, or interns may also provide care. Fellows are doctors who receive training in a special area of medicine after their residency training. Residents are doctors who have recently graduated from medical school and are training in a medical specialty. Interns are first-year residents.

Nurses work closely with doctors to supervise the care provided in the hospital. Nurses take the patient's **vital signs**, administer medications, provide treatments, and teach patients how to care for themselves. The head nurse, also called the clinical nurse manager, coordinates care for each patient on the nursing unit.

Other health care providers include medical technologists, radiographers, and nuclear medicine technicians who perform diagnostic tests, therapists such as physical therapists, occupational therapists, and speech therapists who provide specialized care as needed, and dietitians who provide nutrition counseling and nutrition assessments. There are several other health care providers who may assist patients during their hospital stay; patients should ask for more information about the types of providers they may be in contact with during the time they are in the hospital.

### *Information for visitors and family members*

It may be helpful for the patient to select a spokesperson from the family to communicate with the health care providers. This may improve communication with the health care providers as well as with other family members. The patient should also communicate his or her wishes regarding the spokesperson's telephone communications to other family members.

Educational classes may be available for family members to learn more about the patient's condition and what to expect during the patient's **recovery at home**.

If a family member needs to contact the patient or the patient's other family members, the family member should call the hospital and ask for the nursing unit where the patient is staying. The nursing unit staff can connect the caller to the patient's room, take a message, or connect the caller to the patient's family members who are present. Since every hospital has **patient confidentiality** rules, some information may not be able to be disclosed over the telephone.

Most hospitals prohibit the use of cellular phones in patient care areas, as they interfere with the operation of medical equipment.

Most hospitals are smoke-free environments. There are usually designated outside areas where visitors can smoke.

Most hospitals have designated visiting hours that should be adhered to by family members and friends.

Most hospitals have on-site pharmacies where family members can fill the patient's prescriptions, gift shops, and a cafeteria. Usually a list of on-site and off-site dining options can be obtained from the hospital's information desk or social work department.

### *Preadmission testing*

Preadmission testing includes a review of the patient's medical history, a complete **physical examination**, a variety of tests, patient education, and meetings with the health care team. The review of the patient's

medical history includes an evaluation of the patient's previous and current medical conditions, surgeries and procedures, medications, and any other health conditions such as allergies that may impact the patient's hospital stay. Preadmission testing is generally scheduled for a few days before the hospital admission.

The patient may find it helpful to bring along a family member or friend to the preadmission testing appointments. This caregiver can help the patient remember important details to prepare for the hospital stay.

### *Preadmission instructions*

Preadmission instructions include information about reserving blood products if necessary, taking or discontinuing medications, eating and drinking, **smoking cessation**, limiting activities, and preparing items to bring to the hospital.

### *Blood transfusions and blood donation*

Blood transfusions may be necessary during surgery. A blood **transfusion** is the delivery of whole blood or blood components to replace blood lost through trauma, surgery, or disease. About one in three hospitalized patients will require a blood transfusion. The surgeon can provide an estimate of how much blood the patient's procedure may require.

To decrease the risk of infection and immunologic complications, some hospitals offer a **blood donation** program if surgery is scheduled or if it is known that blood products will be needed by the patient during his or her hospital stay. Autologous blood (from the patient) is the safest blood available for transfusion, since there is no risk of disease transmission. Methods of autologous donation or collection include:

- **Intraoperative blood collection:** The blood lost during surgery is processed, and the red blood cells are re-infused during or immediately after surgery.
- **Preoperative donation:** The patient donates blood once a week for about one to three weeks before surgery. The blood is separated and the blood components needed are re-infused during surgery.
- **Immediate preoperative hemodilution:** The patient donates blood immediately before surgery to decrease the loss of red blood cells during surgery. Immediately after donating, the patient receives fluids to compensate for the amount of blood removed. Since the blood is diluted, fewer red blood cells are lost from bleeding during surgery.
- **Postoperative blood collection:** Blood lost from the surgical site right after surgery is collected and re-infused after the surgical site has been closed.

The physician determines what type of blood collection process, if any, is appropriate.

### *Medication guidelines*

Depending on the reason for the hospital stay, certain medications may be prescribed or restricted. The health care team will provide specific guidelines. If certain medications need to be restricted before the hospital stay, the patient will receive a complete list of the medications (including prescription, over-the-counter, and herbal medications) to avoid taking. The patient should not bring any medications to the hospital unless specifically instructed to by the hospital staff. In the majority of cases all necessary medications, as ordered by the doctor, will be provided in the hospital.

### *Eating and drinking guidelines*

Before most procedures, the patient is advised not to eat or drink anything after midnight the evening before the surgery. This includes no smoking and no gum chewing. The patient should not drink any alcoholic beverages for at least 24 hours before being hospitalized, unless instructed otherwise.

### *Smoking cessation*

Patients are encouraged to quit smoking and stop using tobacco products prior to their hospital admission and to make a commitment to be a nonsmoker. Quitting smoking will help the patient recover more quickly. There are usually several community-based smoking cessation programs available. Members of the hospital staff are more than happy to recommend a program to fit the patient's needs.

### *Activity*

The patient should eat healthy foods, rest, and **exercise** as normal before a hospitalization, unless given other instructions. The patient should try to get enough sleep, although this can often be difficult if the patient is nervous or anxious about the upcoming hospital stay.

The patient should make arrangements ahead of time for someone to care for children and take care of any other necessary activities at home such as getting the mail or newspapers. The patient should inform family members about the scheduled hospital stay, so they can provide help and support.

### *Items to bring to the hospital*

The patient should bring a list of current medications, allergies, and appropriate medical records upon

admission to the hospital. The patient should also bring a prepared list of questions to ask.

The patient should not bring valuables such as jewelry, credit cards, checkbooks, or other such items. A small amount of cash (no more than \$20) may be packed to purchase items such as newspapers or magazines. If necessary, patients can secure their personal belongings in the hospital cashier's office, safe, or vault for safekeeping until discharge. Most hospitals state in their policies that they are not responsible for lost or stolen personal items.

The patient should only pack what is needed. Some essential items include a toothbrush, toothpaste, comb or brush, deodorant, razor (not electric), slippers, robe, pajamas, and one change of comfortable clothes to wear when going home. The patient should also pack eyeglasses, hearing aids, and dentures, including their carrying cases, if applicable. These items should be labeled with the patient's name when not in use, should be stored in their carrying cases, and put in the bedside stand so they are not lost. They should never be placed on food trays because they may be forgotten and thrown out with the food garbage.

The patient should bring a list of family members' names and phone numbers to contact in an emergency. The patient may also want to pack a book or other personal item such as a family picture.

Personal electronic devices such as hair dryers, curling irons, electric razors, personal televisions, computers, and other electronic devices are not permitted in the hospital, since these devices may interfere with the hospital's medical equipment.

### *Transportation*

The patient should arrange for transportation home, since the effects of certain medications given in the hospital make it unsafe to drive.

### **Hospital registration and admission**

Upon arriving at the hospital, the patient first reports to the hospital registration or admitting area. The patient will be required to complete paperwork and show an insurance identification card, if insured. Often, a pre-registration process performed prior to the date of hospital admission helps make the registration process run smoothly. An identification bracelet that includes the patient's name and doctor's name will be placed on the patient's wrist.

If the patient is not feeling well upon arrival to the hospital, a family member or caregiver can help the patient complete the admitting process. Sometimes, a

patient's illness may require that the hospital stay be rescheduled.

### *Informed consent*

The health care provider will review the informed consent form and ask the patient to sign it. Informed consent is an educational process between health care providers and patients. Before any procedure is performed or any form of medical care is provided, the patient is asked to sign a consent form. Before signing the form, the patient should understand the nature and purpose of the procedure or treatment, the risks and benefits of the procedure, and alternatives, including the option of not proceeding with the procedure. Signing the informed consent form indicates that the patient understands and permits the surgery or procedure to be performed. During the discussion about the procedure, health care providers are available to answer the patient's questions about the consent form or procedure.

### *Advance directives*

As part of the admissions process, the patient will be asked about advance directives. Advance directives are legal documents that increase a patient's control over medical decisions. A patient may decide medical treatment in advance, in the event that he or she becomes physically or mentally unable to communicate his or her wishes. Advance directives either state what kind of treatment the patient wants to receive (**living will**), or authorize another person to make medical decisions for the patient when he or she is unable to do so (**durable power of attorney**).

Advance directives are not required and may be changed or canceled at any time. Any change should be written, signed, and dated in accordance with state law, and copies should be given to the physician and to others who received original copies. Advance directives can be revoked either in writing or by destroying the document.

Advance directives are not do-not-resuscitate (DNR) orders. A **DNR order** indicates that a person—usually with a terminal illness or other serious medical condition—has decided not to have **cardiopulmonary resuscitation** (CPR) performed in the event that his or her heart or breathing stops.

### *Admission tests*

Some routine tests will be performed, including blood pressure, temperature, pulse, and weight checks, blood tests, **urinalysis**, **chest x ray**, and **electrocardiogram** (ECG). A brief physical exam will be performed.

## QUESTIONS TO ASK THE DOCTOR

- How can I prepare myself for the hospital stay?
- Who are the members of the health care team at this hospital?
- What types of questions should I ask my insurance provider to determine if the medical expenses of my hospital stay will be covered?
- What type of tests or procedures will be performed?
- What types of precautions must I follow before and after my hospital stay?
- Will I have to have blood transfusions during my hospital stay?
- Can I take my medications the day I am admitted to the hospital?
- Should I change my diet or eating habits before my hospital stay?
- How long will I have to stay in the hospital?
- What kind of pain or discomfort will I experience and what can I take to relieve it?
- What types of resources are available to me during my hospital stay, and during my recovery at home?
- After I go home from the hospital, how long will it take me to recover?
- What are the signs of infection, and what types of symptoms should I report to my doctor?
- What types of medications will I have to take? How long will I have to take them?
- When will I be able to resume my normal activities? When will I be able to drive? When will I be able to return to work?
- What lifestyle changes (including diet, weight management, exercise, and activity changes) are recommended to improve my condition?
- How often do I need to see my doctor for follow-up visits?

The health care team will ask several questions to evaluate the patient's condition. The patient should inform the health care team if he or she drinks alcohol on a daily basis so precautions can be taken to avoid complications.

### Results

Patients who receive proper preparation for their hospital experience, including physical and psychological preparation, are less anxious and are more likely to make a quicker recovery at home, with fewer complications.

## Plastic, reconstructive, and cosmetic surgery

### Definition

Plastic, reconstructive, and cosmetic surgery procedures are a variety of operations performed in order to repair or restore body parts to look normal, or to

change a body part to look better. These types of surgery are highly specialized. They are characterized by careful preparation of a person's skin and tissues, by precise cutting and suturing techniques, and by care taken to minimize scarring. Recent advances in the development of miniaturized instruments, new materials for artificial limbs and body parts, and improved surgical techniques have expanded the range of plastic surgery procedures that can be performed.

### Purpose

Although these three types of surgery share some common techniques and approaches, they have somewhat different emphases. Plastic surgery is usually performed to treat birth defects and to remove skin blemishes such as warts, acne scars, or birthmarks. Cosmetic surgery procedures are performed to make persons look younger or enhance their appearance in other ways. Reconstructive surgery is used to reattach body parts severed in combat or accidents, to perform skin grafts after severe burns, or to reconstruct parts of person's body that were missing at birth or removed by surgery. Reconstructive surgery is the oldest form of plastic surgery, having developed out of the need to treat wounded soldiers in wartime.

### Demographics

The top 10 most commonly performed elective cosmetic surgeries in the United States include the following:

- liposuction
- breast augmentation
- eyelid surgery
- face lift
- tummy tuck
- collagen injections
- chemical peel
- laser skin resurfacing
- rhinoplasty
- forehead lift

There were approximately 31 million surgical procedures performed in the United States in 2006. Because many plastic and reconstructive surgical procedures are performed in private professional offices or as outpatient procedures, accurate statistics concerning the number of procedures performed are not available.

## KEY TERMS

**Blepharoplasty**—Surgical reshaping of the eyelid.

**Dermabrasion**—A technique for removing the upper layers of skin with planing wheels powered by compressed air.

**Face lift**—Plastic surgery performed to remove sagging skin and wrinkles from an individual's face.

**Liposuction**—A surgical technique for removing fat from under the skin by vacuum suctioning.

**Mammoplasty**—Surgery performed to change the size or shape of breasts.

**Rhinoplasty**—Surgery performed to change the shape of the nose.

### Description

#### *Plastic surgery*

Plastic surgery includes a number of different procedures that usually involve skin. Operations to remove excess fat from the abdomen ("tummy tucks"), **dermabrasion** to remove acne scars or tattoos, and reshaping the cartilage in children's ears (**otoplasty**) are common applications of plastic surgery.

#### *Cosmetic surgery*

Most cosmetic surgery is done on the face. It is intended either to correct disfigurement or to enhance a person's features. The most common cosmetic procedure for children is correction of a cleft lip or palate. In adults, the most common procedures are remodeling of the nose (**rhinoplasty**), removal of baggy skin around the eyelids (**blepharoplasty**), face lifts (rhytidectomy), or changing the size or shape of the breasts (mammoplasty). Although many people still think of cosmetic surgery as only for women, growing numbers of men are choosing to have face lifts and eyelid surgery, as well as hair transplants and "tummy tucks."

#### *Reconstructive surgery*

Reconstructive surgery is often performed on burn and accident victims. It may involve the rebuilding of severely fractured bones, as well as **skin grafting**. Reconstructive surgery includes such procedures as the reattachment of an amputated finger or toe, or implanting a prosthesis. Prostheses are artificial structures and materials that are used to replace missing limbs or teeth, or arthritic hip and knee joints.

## Diagnosis/Preparation

### General preparation

Preparation for nonemergency plastic or reconstructive surgery includes individual education, as well as medical considerations. Some operations, such as nose reshaping or the removal of warts, small birthmarks, and tattoos can be done as outpatient procedures under **local anesthesia**. Most plastic and reconstructive surgery, however, involves a stay in the hospital and **general anesthesia**.

### Medical preparation

Preparation for plastic surgery includes the surgeon's detailed assessment of the parts of an individual's body that will be involved. Skin grafts require evaluating suitable areas of skin for the right color and texture to match the skin at the graft site. Face lifts and cosmetic surgery in the eye area require very close attention to the texture of the skin and the placement of surgical cuts (incisions).

Persons scheduled for plastic surgery under general anesthesia will be given a **physical examination**, blood and urine tests, and other tests to make sure that they do not have any previously undetected health problems or blood clotting disorders. The surgeon will check the list of prescription medications that the prospective patient may be taking to make sure that none of them will interfere with normal blood clotting or interact with the anesthetic.

Individuals are asked to avoid using **aspirin** or medications containing aspirin for a week to two weeks before surgery, because these drugs lengthen the time of blood clotting. Smokers are asked to stop smoking two weeks before surgery because smoking interferes with the healing process. For some types of plastic surgery, individuals may be asked to donate several units of their own blood before the procedure, in case a **transfusion** is needed during the operation. The prospective patient will be asked to sign a consent form before the operation.

### Personal education

The surgeon will meet with the prospective patient before the operation is scheduled, in order to explain the procedure and to be sure that the individual is realistic about the expected results. This consideration is particularly important for people undergoing cosmetic surgery.

### Medical considerations

Some people should not have plastic surgery because of certain medical risks. These groups include:

- persons recovering from a heart attack, severe infection (for example, pneumonia), or other serious illnesses
- people with infectious hepatitis or HIV infections
- individuals with cancer whose cancer might spread (metastasize)
- people who are extremely overweight (Individuals who are more than 30% overweight should not have liposuction.)
- persons with blood clotting disorders

### Psychological

Plastic, cosmetic, and reconstructive surgeries have an important psychological dimension because of the high value placed on outward appearance in Western society. Many people who are born with visible deformities or disfigured by accidents later in life develop emotional problems related to social rejection. Other people work in fields such as acting, modeling, media journalism, and even politics, where their employment depends on how they look. Some people have unrealistic expectations of cosmetic surgery and think that it will solve all their life problems. It is important for anyone considering non-emergency plastic or cosmetic surgery to be realistic about its results. One type of psychiatric disorder, called body dysmorphic disorder, is characterized by an excessive preoccupation with imaginary or minor flaws in appearance. Persons with this disorder frequently seek unnecessary plastic surgery.

## Aftercare

### Medical

Medical aftercare following plastic surgery under general anesthesia includes bringing patients to a **recovery room**, monitoring their **vital signs**, and giving medications to relieve pain as necessary. Persons who have had fat removed from the abdomen may be kept in bed for as long as two weeks. Individuals who have had mammoplasties, **breast reconstruction**, and some types of facial surgery typically remain in the hospital for a week after the operation. Those who have had **liposuction** or eyelid surgery are usually sent home in a day or two.

People who have had outpatient procedures are usually given **antibiotics** to prevent infection and are sent home as soon as their vital signs are normal.

### Psychological

Some individuals may need follow-up psychotherapy or counseling after plastic or reconstructive surgery. These people typically include children whose schooling and social relationships have been affected

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

Plastic, reconstructive, and cosmetic surgical procedures are performed by surgeons with specialized training in plastic and reconstructive surgery. Depending on the complexity of the procedures, they may be performed in hospitals as an inpatient, in outpatient facilities, or in private professional offices.

by birth defects, as well as persons of any age whose deformities or disfigurements were caused by trauma from accidents, war injuries, or violent crimes.

### Risks

The risks associated with plastic, cosmetic, and reconstructive surgery include the postoperative complications that can occur with any surgical operation under anesthesia. These complications include wound infection, internal bleeding, pneumonia, and reactions to the anesthesia.

In addition to these general risks, some plastic, cosmetic, and reconstructive surgical procedures carry specific risks:

- formation of undesirable scar tissue
- development of persistent pain, redness, or swelling in the area of the surgery
- infection inside the body related to inserting a prosthesis (These infections can result from contamination at the time of surgery or from bacteria migrating into the area around the prosthesis at a later time.)
- anemia or fat embolisms from liposuction
- rejection of skin grafts or tissue transplants
- loss of normal feeling or function in the area of the operation (For example, it is not unusual for women who have had mammoplasties to lose sensation in their nipples.)
- complications resulting from unforeseen technological problems (The best-known example of this problem was the discovery in the mid-1990s that breast implants made with silicone gel could leak into the recipient's body.)

### Normal results

Normal results include an individual's recovery from the surgery with satisfactory results and without complications.

## QUESTIONS TO ASK THE DOCTOR

- What will be the resulting appearance?
- Is the surgeon board certified in plastic and reconstructive surgery?
- How many similar procedures has the surgeon performed?
- What is the surgeon's complication rate?

### Morbidity and mortality rates

Morbidity and mortality rates vary with the complexity and severity of different procedures. Mortality is similar to that associated with all surgical procedures. Morbidity is influenced by personal expectations. From a surgical perspective, most morbidity is due to errors associated with anesthesia, procedure, pain medications, and after care. From an individual's perspective, morbidity involves the degree to which actual results compared to expected outcomes. The latter distinction is very subjective.

### Alternatives

Alternatives to plastic, reconstructive, and cosmetic surgical procedures include using various products that may be affixed to articles of clothing or the surface of the body.

# Pneumectomy

## Definition

Pneumectomy is the medical term for the surgical removal of a lung.

## Purpose

A pneumectomy is most often used to treat lung cancer when less radical surgery cannot achieve satisfactory results. It may also be the most appropriate treatment for a tumor located near the center of the lung that affects the pulmonary artery or veins, which transport blood between the heart and lungs. In addition, pneumectomy may be the treatment of choice when the patient has a traumatic chest injury that has damaged the main air passage (bronchus) or the lung's major blood vessels so severely that they cannot be repaired.

## Demographics

Pneumonectomies are usually performed on patients with lung cancer, as well as patients with such noncancerous diseases as chronic obstructive pulmonary disease (COPD), which includes emphysema and chronic bronchitis. These diseases cause airway obstruction.

Approximately 342,000 Americans die of lung disease every year. Lung disease is responsible for one in seven deaths in the United States, according to the American Lung Association. This makes lung disease America's number three killer. More than 35 million Americans are now living with chronic lung disease.

## Lung cancer

Lung cancer is the leading cause of cancer-related deaths in the United States. It is projected to claim more than nearly 158,160,300 lives in 2007. Lung cancer kills more people than cancers of the breast, prostate, colon, and pancreas combined. Cigarette smoking accounts for nearly 90% of cases of lung cancer in the United States.

Lung cancer is the second most common cancer among both men and women and is the leading cause of **death** from cancer in both sexes. In addition to the use of tobacco as a major cause of lung cancer among smokers, second-hand smoke contributes to the development of lung cancer among nonsmokers. Exposure to asbestos and other hazardous substances is also known to cause lung cancer. Air pollution is also a probable cause, but makes a relatively small contribution to incidence and mortality rates. Indoor exposure to radon may also make a small contribution to the total incidence of lung cancer in certain geographic areas of the United States.

In each of the major racial/ethnic groups in the United States, the rates of lung cancer among men are about two to three times greater than the rates among women. Among men, age-adjusted lung cancer incidence

## KEY TERMS

**Bronchodilator**—A drug that relaxes bronchial muscles resulting in expansion of the bronchial air passages.

**Bronchopleural fistula**—An abnormal connection between an air passage and the membrane that covers the lungs.

**Corticosteroids**—Any of various adrenal-cortex steroids used as anti-inflammatory agents.

**Emphysema**—A chronic disease characterized by loss of elasticity and abnormal accumulation of air in lung tissue.

**Empyema**—An accumulation of pus in the lung cavity, usually as a result of infection.

**Malignant mesothelioma**—A cancer of the pleura (the membrane lining the chest cavity and covering the lungs) that typically is related to asbestos exposure.

**Pleural space**—The small space between the two layers of the membrane that covers the lungs and lines the inner surface of the chest.

**Pulmonary embolism**—Blockage of a pulmonary artery by a blood clot or foreign matter.

**Pulmonary rehabilitation**—A program to treat COPD, which generally includes education and counseling, exercise, nutritional guidance, techniques to improve breathing, and emotional support.

rates (per 100,000) range from a low of about 14 among Native Americans to a high of 117 among African Americans, an eight-fold difference. For women, the rates range from approximately 15 per 100,000 among Japanese Americans to nearly 51 among Native Alaskans, only a three-fold difference.

### *Chronic obstructive pulmonary disease*

The following are risk factors for COPD:

- current smoking or a long-term history of heavy smoking
- employment that requires working around dust and irritating fumes
- long-term exposure to second-hand smoke at home or in the workplace
- a productive cough (with phlegm or sputum) most of the time
- shortness of breath during vigorous activity

- shortness of breath that grows worse even at lower levels of activity
- a family history of early COPD (before age 45)

## Diagnosis/Preparation

### *Diagnosis*

In some cases, the diagnosis of a lung disorder is made when the patient consults a physician about chest pains or other symptoms. The symptoms of lung cancer vary somewhat according to the location of the tumor; they may include persistent coughing, coughing up blood, wheezing, fever, and weight loss. In cases involving direct trauma to the lung, the decision to perform a pneumectomy may be made in the emergency room. Before scheduling a pneumectomy, however, the surgeon reviews the patient's medical and surgical history and orders a number of tests to determine how successful the surgery is likely to be.

In the case of lung cancer, blood tests, a bone scan, and computed tomography scans of the head and abdomen indicate whether the cancer has spread beyond the lungs. **Positron emission tomography (PET)** scanning is also used to help stage the disease. Cardiac screening indicates how well the patient's heart will tolerate the procedure, and extensive pulmonary testing (e.g., breathing tests and quantitative ventilation/perfusion scans) predicts whether the remaining lung will be able to make up for the patient's diminished ability to breathe.

### *Preparation*

A patient who smokes must stop as soon as a lung disease is diagnosed. Patients should not take **aspirin** or ibuprofen for seven to 10 days before surgery. Patients should also consult their physician about discontinuing any blood-thinning medications such as Coumadin or warfarin. The night before surgery, patients should not eat or drink anything after midnight.

## Description

In a conventional pneumectomy, the surgeon removes only the diseased lung itself. In a partial pneumectomy, one or more lobes of a lung are removed. In an extrapleural pneumectomy, the surgeon removes the lung, part of the membrane covering the heart (pericardium), part of the diaphragm, and the membrane lining the chest cavity (parietal pleura). Either operation is extensive, and require that the patient be given **general anesthesia**. An intravenous line inserted into one arm supplies fluids and medication throughout the operation, which usually lasts one to three hours.

The surgeon begins the operation by cutting a large opening on the same side of the chest as the diseased lung. This posterolateral **thoracotomy** incision extends from a point below the shoulder blade around the side of the patient's body along the curvature of the ribs at the front of the chest. Sometimes the surgeon removes part of the fifth rib in order to have a clearer view of the lung and greater ease in removing the diseased organ.

A surgeon performing a traditional pneumectomy then:

- deflates (collapses) the diseased lung
- ties off the lung's major blood vessels to prevent bleeding into the chest cavity
- clamps the main bronchus to prevent fluid from entering the air passage
- cuts through the bronchus
- removes the lung
- staples or sutures the end of the bronchus that has been cut
- makes sure that air is not escaping from the bronchus
- inserts a temporary drainage tube between the layers of the pleura (pleural space) to draw air, fluid, and blood out of the surgical cavity
- closes the chest incision

### Aftercare

Chest tubes drain fluid from the incision and a respirator helps the patient breathe for at least 24 hours after the operation. The patient may be fed and medicated intravenously. If no complications arise, the patient is transferred from the surgical **intensive care unit** to a regular hospital room within one to two days.

A patient who has had a conventional pneumectomy will usually leave the hospital within 10 days. Aftercare during hospitalization is focused on:

- relieving pain
- monitoring the patient's blood oxygen levels
- encouraging the patient to walk in order to prevent formation of blood clots
- encouraging the patient to cough productively in order to clear accumulated lung secretions

If the patient cannot cough productively, the doctor uses a flexible tube (bronchoscope) to remove the lung secretions and fluids.

Recovery is usually a slow process, with the remaining lung gradually taking on the work of the lung that has been removed. The patient may gradually resume

normal non-strenuous activities. A pneumectomy patient who does not experience postoperative problems may be well enough within eight weeks to return to a job that is not physically demanding; however, 60% of all pneumectomy patients continue to struggle with shortness of breath six months after having surgery.

### Risks

The risks for any surgical procedure requiring anesthesia include reactions to the medications and breathing problems. The risks for any surgical procedure include bleeding and infection.

Between 40% and 60% of pneumectomy patients experience such short-term postoperative difficulties as:

- prolonged need for a mechanical respirator
- abnormal heart rhythm (cardiac arrhythmia); heart attack (myocardial infarction); or other heart problem
- pneumonia
- infection at the site of the incision
- a blood clot in the remaining lung (pulmonary embolism)
- an abnormal connection between the stump of the cut bronchus and the pleural space due to a leak in the stump (bronchopleural fistula)
- accumulation of pus in the pleural space (empyema)
- kidney or other organ failure

Over time, the remaining organs in the patient's chest may move into the space left by the surgery. This condition is called postpneumectomy syndrome; the surgeon can correct it by inserting a fluid-filled prosthesis into the space formerly occupied by the diseased lung.

### Normal results

The doctor will probably advise the patient to refrain from strenuous activities for a few weeks after the operation. The patient's rib cage will remain sore for some time.

A patient whose lungs have been weakened by noncancerous diseases like emphysema or chronic bronchitis may experience long-term shortness of breath as a result of this surgery. On the other hand, a patient who develops a fever, chest pain, persistent cough, or shortness of breath, or whose incision bleeds or becomes inflamed, should notify his or her doctor immediately.

## WHO PERFORMS THE SURGERY AND WHERE IS IT PERFORMED?

Pneumonectomies are performed in a hospital by a thoracic surgeon, who is a physician who specializes in chest, heart, and lung surgery. Thoracic surgeons may further specialize in one area, such as heart surgery or lung surgery. They are board-certified through the Board of Thoracic Surgery, which is recognized by the American Board of Medical Specialties. A doctor becomes board certified by completing training in a specialty area and passing a rigorous examination.

## Morbidity and mortality rates

In the United States, the immediate survival rate from surgery for patients who have had the left lung removed is between 96% and 98%. Due to the greater risk of complications involving the stump of the cut bronchus in the right lung, between 88% and 90% of patients survive removal of this organ. Following lung volume reduction surgery, most investigators now report mortality rates of 5–9%.

## Alternatives

### *Lung cancer*

The treatment options for lung cancer are surgery, radiation therapy, and chemotherapy, either alone or in combination, depending on the stage of the cancer.

After the cancer is found and staged, the cancer care team discusses the treatment options with the patient. In choosing a treatment plan, the most significant factors to consider are the type of lung cancer (small cell or non-small cell) and the stage of the cancer. It is very important that the doctor order all the tests needed to determine the stage of the cancer. Other factors to consider include the patient's overall physical health; the likely side effects of the treatment; and the probability of curing the disease, extending the patient's life, or relieving his or her symptoms.

### *Chronic obstructive pulmonary disease*

Although surgery is rarely used to treat COPD, it may be considered for people who have severe symptoms that have not improved with medication therapy. A significant number of patients with advanced COPD face a miserable existence and are at high risk of death, despite advances in medical technology. This

## QUESTIONS TO ASK THE DOCTOR

- Why is it necessary to remove the whole lung?
- What benefits can I expect from a pneumonectomy?
- What are the risks of this operation?
- What are the normal results?
- How long will my recovery take?
- Are there any alternatives to this surgery?

group includes patients who remain symptomatic despite the following:

- smoking cessation
- use of inhaled bronchodilators
- treatment with antibiotics for acute bacterial infections, and inhaled or oral corticosteroids
- use of supplemental oxygen with rest or exertion
- pulmonary rehabilitation

After the severity of the patient's airflow obstruction has been evaluated, and the foregoing interventions implemented, a pulmonary disease specialist should examine him or her, with consideration given to surgical treatment.

Surgical options for treating COPD include laser therapy or the following procedures:

- **Bullectomy.** This procedure removes the part of the lung that has been damaged by the formation of large air-filled sacs called bullae.
- **Lung volume reduction surgery.** In this procedure, the surgeon removes a portion of one or both lungs, making room for the remaining lung tissue to work more efficiently. Its use is considered experimental, although it has been used in selected patients with severe emphysema.
- **Lung transplant.** In this procedure a healthy lung from a donor who has recently died is given to a person with COPD.

Portacaval shunting see **Portal vein bypass**

## Portal vein bypass

### Definition

Portal vein bypass surgery diverts blood from the portal vein into another vein. It is performed when pressure in the portal vein is so high that it causes internal bleeding from blood vessels in the esophagus (the tube that brings food from the mouth to the stomach).

### Purpose

The portal vein carries blood from the stomach and abdominal organs to the liver. It is a major vein that splits into many branches. In people with liver failure and cirrhosis, a chronic degenerative liver disease causing irreversible scarring of the liver, the liver is incapable of processing blood from the bowels. As a result, an abnormally high pressure develops in the veins that drain blood from the bowels as the body tries to form other channels for the blood to empty into the main circulation. These channels consist of fragile veins that surround the esophagus, stomach, or other areas of the digestive tract. Because of the fragility of these veins, they are prone to rupturing, which can result in massive amounts of bleeding. The abnormally high pressure within the veins draining into the liver, called portal hypertension, can also result in the formation of fluid seeping from the surface of the liver and collecting in large quantities in the abdominal cavity, a condition known as ascites.

Massive internal bleeding caused by portal hypertension occurs in about 40% of patients with cirrhosis. It is initially fatal in at least half of these patients. Patients who survive are likely to experience bleeding recurrence. Portal vein bypass, also called portacaval shunting, is performed on these surviving patients to control bleeding.

The purpose of portal vein bypass surgery is to lower portal hypertension by shunting blood away from the portal venous system and into the main venous system.

### Demographics

Cirrhosis of the liver is caused by chronic liver disease. Common causes of chronic liver disease in the United States include hepatitis C infection and long-term alcohol abuse. Men and women are equally affected, but onset is earlier in men.

### Description

Different portal vein bypass procedures are available. The surgery is usually performed under **general anesthesia**. The surgeon makes an abdominal incision and locates the portal vein. In portacaval shunting, blood from the portal vein is diverted into the inferior vena cava (one of the main veins leading back to the heart). This is the most common type of bypass. In splenorenal shunting, the splenic vein (a part of the portal vein) is connected to the renal (kidney) vein. A mesocaval shunt connects the superior mesenteric vein (another part of the portal vein) to the inferior vena cava.

Another procedure, called tranjugular intrahepatic portosystemic shunt (TIPS), has become the favored surgical approach. A TIPS is performed

Portal vein bypass can be achieved through one of two incisions (A). Once the abdomen is entered, the inferior vena cava is exposed (B). Further exposure reveals the portal vein. Both the portal vein and inferior vena cava are clamped (C). Windows are cut in both vessels (D), and the two are connected with sutures (E). (Illustration by GGS Information Services. Cengage Learning, Gale.)

## KEY TERMS

**Ascites**—Fluid buildup in the abdominal cavity caused by fluid leaks from the surface of the liver and intestine.

**Cirrhosis**—A chronic degenerative liver disease causing irreversible scarring of the liver.

**Inferior vena cava**—A large vein that returns blood from the legs, pelvis, and abdomen to the heart.

**Portal hypertension**—Abnormally high pressure within the veins draining into the liver.

**Portal vein**—A large vein that carries blood from the stomach and intestines to the liver.

**Varices**—Uneven, permanent dilation of veins.

through a small nick in the skin, working through specialized instruments that are passed through the body using an x-ray camera for guidance. The TIPS procedure creates a shunt within the liver itself, by linking the portal vein with a vein draining away from the liver together with a device called a stent, which acts as a scaffold to support the connection between these two veins inside the liver.

## Diagnosis/Preparation

A radiologist assesses patients for bypass surgery based on their medical history, **physical examination**, blood work, and liver imaging studies performed using computed tomography (CT) scans, ultrasounds, or **magnetic resonance imaging** (MRI) scans, and in consultation with the treating gastroenterologist, hepatologist, or surgeon.

Standard preoperative blood and urine tests are also performed. The heart and arterial blood pressure are monitored both during and after the operation.

## Aftercare

The patient is connected to a heart monitor and fed through a nasogastric tube. Vital functions are monitored through blood and urine tests. Patients receive pain medication and **antibiotics**. Once released from the hospital, patients are expected to abstain from alcohol and to follow a diet and medication schedule designed to reduce the risks of bleeding.

## Risks

Portal vein bypass surgery is high risk because it is performed on patients who are generally in poor

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

Portal vein bypass surgery is performed by a surgeon specialized in gastroenterology or hepatology in a hospital setting, very often as an emergency operation.

health. Those patients who survive the operation still face the risk of heart failure, brain disease due to a decrease in the liver's conversion of waste products (liver encephalopathy), hemorrhage, lung complications, infection, coma, and **death**.

## Normal results

More than 90% of patients that undergo TIPS to prevent bleeding from varices will have a relief in their symptoms and experience little to no bleeding after surgery. When TIPS is performed for ascites, 60–80% of people will have relief in their ascites. The survival rate is directly related to the amount of liver damage patients have; the less damage, the more likely the patient is to recover. Cooperation with restrictions on alcohol and diet affect long-term survival.

## Morbidity and mortality rates

Liver cirrhosis is a major medical problem worldwide and is associated with significant morbidity and mortality from its complications such as liver cell insufficiency and portal hypertension with ascites and gastrointestinal bleeding.

## Alternatives

Before resorting to bypass surgery, physicians first attempt to treat portal hypertension with medications known as nonselective beta-blockers. These medications need to be taken daily to produce an effect and some patients may not be able to remain on beta-blocker therapy if they develop side effects. Other patients on beta-blocker therapy also remain at risk for bleeding from varices and from ascites.

Another approach is to seal off the veins to prevent rupturing. In sclerotherapy, a camera (endoscope) is passed down through the esophagus to inject the abnormal veins with substances that close them off. This can also be achieved with variceal band ligation, a procedure by which the abnormal veins are tied off with small rubber bands. Although sclerotherapy and variceal

## QUESTIONS TO ASK THE DOCTOR

- What are the possible complications involved in portal vein bypass surgery?
- Why is the surgery required?
- Are there any alternatives?
- What type of anesthesia will be used?
- How is the surgery performed?
- How long will I be in the hospital?
- How much portal vein bypass surgery do you perform in a year?

band ligation are very effective in targeting the abnormal and fragile veins around the esophagus, they do not lower the pressure of the blood inside the portal venous system. Thus, portal hypertension may still result in fluid accumulation inside the abdominal cavity, or in bleeding.

The best approach to relieve portal hypertension within a patient is by replacing their liver with a new one capable of filtering the blood. However, not many patients are suitable candidates for a liver transplant.

## Positron emission tomography (PET)

### Definition

Positron emission tomography (PET) is a non-invasive scanning technique that utilizes small amounts of radioactive positrons (positively charged particles) to visualize body function and metabolism.

### Purpose

PET is the fastest growing nuclear medicine tool in terms of increasing acceptance and applications. It is useful in the diagnosis, staging, and treatment of cancer because it provides information that cannot be obtained by other techniques such as computed tomography (CT) and **magnetic resonance imaging (MRI)**.

PET scans are performed at medical centers equipped with a small cyclotron. Smaller cyclotrons and increasing availability of certain radiopharmaceuticals are making PET a more widely used imaging modality.

Physicians first used PET to obtain information about brain function, and to study brain activity in various neurological diseases and disorders including stroke, epilepsy, Alzheimer's disease, Parkinson's disease, and Huntington's disease; and in psychiatric disorders such as schizophrenia, depression, obsessive-compulsive disorder, attention deficit hyperactivity disorder (ADHD), and Tourette syndrome. PET is now used to evaluate patients for these cancers: head and neck, lymphoma, melanoma, lung, colorectal, breast, and esophageal. PET also is used to evaluate heart muscle function in patients with coronary artery disease or cardiomyopathy.

### Description

PET involves injecting a patient with a radiopharmaceutical similar to glucose. An hour after injection of this tracer, a PET scanner images a specific metabolic function by measuring the concentration and distribution of the tracer throughout the body.

When it enters the body, the tracer courses through the bloodstream to the target organ, where it emits positrons. The positively charged positrons collide with negatively charged electrons, producing gamma rays. The gamma rays are detected by photo-multiplier-scintillator combinations positioned on opposite sides of the patient. These signals are processed by the computer and images are generated.

## KEY TERMS

**Electron**—One of the small particles that make up an atom. An electron has the same mass and amount of charge as a positron, but the electron has a negative charge.

**Gamma ray**—A high-energy photon emitted by radioactive substances.

**Half-life**—The time required for half of the atoms in a radioactive substance to disintegrate.

**Photon**—A light particle.

**Positron**—One of the small particles that make up an atom. A positron has the same mass and amount of charge as an electron, but the positron has a positive charge.

PET provides an advantage over CT and MRI because it can determine if a lesion is malignant. The two other modalities provide images of anatomical structures, but often cannot provide a determination of malignancy. CT and MRI show structure, while PET shows function. PET has been used in combination with CT and MRI to identify abnormalities with more precision and indicate areas of most active metabolism. This additional information allows for more accurate evaluation of cancer treatment and management.

## Post-surgical infections

### Definition

Post-surgical infections are any kind of infection that occurs in the immediate post-operative period. They are an extremely common complication of any type of surgical procedure, striking about 600,000 of the 30 million individuals who undergo surgery annually.

### Description

A mnemonic called the three W's is often used to remember the most common targets of post-surgical infection:

- Wind—Infections of the respiratory system
- Water—Infections of the urinary system
- Wound—Infections involving the incision and surgical site

Other areas prone to infection after surgery include the intravenous site or the site of any other type of port.

There are several reasons why there is a high risk of respiratory infection following surgery:

- The use of **general anesthesia** suppresses the functioning of the mucociliary ladder, allowing mucus and organisms to accumulate
- Suppression of the gag reflex may allow aspiration of saliva into the respiratory tract

- Intubation may inadvertently introduce organisms into the respiratory tract
- Pain following surgery may interfere with an individual's ability to breathe deeply and to cough in order to clear their respiratory tract of excess secretions
- Pain medications further suppress an individual's tendency to breathe deeply

Respiratory infections usually manifest themselves through fever, cough, sputum production, shortness of breath, low blood oxygen. Suspected respiratory infections may be diagnosed through **chest x ray** and sputum culture.

Urinary tract infections are common because of the frequent use of a catheter during surgery, or through the post-operative period. **Post-surgical pain** and the side effects of anesthesia and pain medications may also result in urinary retention, requiring repeated in-and-out catheterization, increasing the risk of urinary tract infection.

Urinary tract infections usually manifest themselves through painful, frequent urine. Urine may appear bloody or cloudy. Suspected urinary tract infections may be diagnosed through **urinalysis** or **urine culture**.

About 2-5% of all surgical patients develop infections at the site of their operation. The following factors increase the risk of wound infection after surgery:

- Patient's age (elderly and newborns have higher risk)
- Weakened immune system
- Skin disease
- Malnutrition
- Co-existing diseases (such as diabetes, cancer)
- Operations involving areas that are already infected
- Transplants
- Implants
- Inadequate **bowel preparation**
- Lengthy surgery
- Use of drains
- Hemorrhage or hematoma during surgery
- Unintentional nick in bowel
- Use of blood transfusion
- Inappropriate use of **antibiotics**
- Poor sterile technique

Wound, incision, or surgical site infections usually manifest themselves as increased pain and tenderness at the site, redness, swelling, pus production, bleeding, and poor wound healing. Diagnosis is often made by

swabbing the area and culturing the pus to identify the specific organism.

Antibiotics are chosen based on either presumptive knowledge of the most common type of organism to cause infection in a given post-surgical setting, or based on the results of cultures of infected material. Antibiotics may be given orally or intravenously, and multiple antibiotics may be required, depending on the organism types and the severity of the infection.

## Post-surgical pain

### Definition

Post-surgical pain is a complex response to tissue trauma during surgery that stimulates hypersensitivity of the central nervous system. The result is pain in areas not directly affected by the surgical procedure. Post-operative pain may be experienced by an inpatient or outpatient. It can be felt after any surgical procedure, whether it is minor dental surgery or a triple-bypass heart operation.

### Purpose

Postoperative pain increases the possibility of post-surgical complications, raises the cost of medical care, and most importantly, interferes with recovery and return to normal activities of daily living. Management of post-surgical pain is a basic patient right. When pain is controlled or removed, a patient is better able to participate in activities such as walking or eating, which will encourage his or her recovery. Patients will also sleep better, which aids the healing process.

## Description

Pain is recognized in two different forms: physiologic pain and clinical pain. Physiologic pain comes and goes, and is the result of experiencing a high-intensity sensation. It often acts as a safety mechanism to warn individuals of danger (e.g., a burn, animal scratch, or broken glass). Clinical pain, in contrast, is marked by hypersensitivity to painful stimuli around a localized site, and also is felt in non-injured areas nearby. When a patient undergoes surgery, tissues and nerve endings are traumatized, resulting in incision pain. This trauma overloads the pain receptors that send messages to the spinal cord, which becomes overstimulated. The resultant central sensitization is a type of posttraumatic stress to the spinal cord, which interprets any stimulation—painful or otherwise—as unpleasant. That is why a patient may feel pain in movement or physical touch in locations far from the surgical site.

Patients handle post-operative pain in highly individualized ways. Health care professionals have observed that some patients report that they are in extreme pain after surgery, demanding large doses of pain medications while others seem to do well with much less medication. Several theories have been put forth to account for this discrepancy. For example, differences in body size seemed to require differing amounts of medication, but this theory did not explain differences in pain perception among patients of the same build. Emotional well-being was considered a better indicator of the ability to tolerate pain. It has been theorized that patients with stronger support systems and better attitudes actually perceive less pain than others. Some health care professionals have even speculated that extreme pain was not real in many cases, but was a way to seek attention.

Clear biological evidence proving that individuals are born with varying thresholds of pain perception was only recently discovered. Psychiatrist and radiologist Jon-Kar Zubieta, from the Mental Health Research Institute at the University of Michigan, found that variations in an amino acid in a newly discovered gene, which codes for an enzyme that accesses neurotransmitters in the brain, produce different levels of pain perception. Only three combinations produce the variation. One individual may be able to fully access and metabolize the opioid neurotransmitters that reduce the sensation of pain. This person would have a higher threshold of pain tolerance and a lower level of pain perception. Another might not be able to do so at all, and that individual would experience more intense pain from the same stimulus. A third person might be able to tolerate a moderate amount of pain.

## KEY TERMS

**Epidural catheter**—A thin plastic tube, through which pain medication is delivered, inserted into the patient's back before surgery.

**Intubation**—Placing a tube in the patient's airway to maintain adequate oxygen intake.

**Opioids**—Narcotic pain medications.

**NSAIDs**—Nonsteroidal anti-inflammatory drugs, popular over-the-counter pain relievers.

**Patient-controlled analgesia (PCA)**—The patient administers a dose of pain medication by pressing a button on a pump, which delivers the medication through a tube attached to either an IV or an epidural catheter.

**Subcutaneous**—Under the skin.

This variation in genes not only shows that individuals do indeed experience pain at different levels, but it also points to differences in how people behave toward other stressors. Genetic variation may be a factor in the impact of long-term illness and depression that often accompanies chronic pain.

Since pain perception is highly subjective, it is important for the health care team to be aware of pain sensitivity differences in patients, and to value patient self-reports as reliable tools for pain assessment. The most common self-report system in use is the pain intensity scale. The patient is asked to identify where the pain falls on a scale of 0 “no pain at all” to 10 “the worst pain in the world.” This scale, however, does have limitations. The Short-Form McGill Questionnaire, which uses sensory words or synonyms, may allow the patient to communicate more accurate, descriptive information about pain and may be a better tool in planning **pain management** strategies.

It is clear that there is a real need for providing different approaches to post-surgical pain management. A variety of interventions may be used before, during, and after surgery. Most of these methods involve medications given orally, intravenously, intramuscularly, or topically (via the skin). Some must be administered by a health care professional, others can be administered by the patient.

## Pain management methods

### *Presurgery pain management*

The goal of post-surgical pain management is to reduce the amount pain a patient experiences after

surgery. New research has suggested that preventing the nervous system from being overtaxed by pain from the trauma of surgery may lead to a less painful post-operative experience. Pretreated patients may require less post-surgical medications, and they may recover more quickly, possibly experiencing pain-free days far sooner than patients who have used traditional post-surgical pain methods.

Also, in view of improved, less-invasive surgical techniques and the insurance industry's attempts to trim rising medical costs by reducing the length of hospital stays, many patients have no longer been required to remain in the hospital overnight after a surgery. Recently, outpatient (also called ambulatory) surgery has become the procedure of choice for many complex surgeries, such as **hysterectomy** and prostatectomy. After ambulatory surgery the must be made comfortable enough to return home and given tools to manage his or her own pain.

Preemptive analgesia introduces anesthetic drugs near the spinal cord or, sometimes, in nerve blocks in specific regions of the body. An epidural catheter, a thin plastic tube through which pain medication is delivered, is inserted into the patient's back before surgery. The patient may also receive **general anesthesia** and post-surgical pain medications as needed. Sometimes, the epidural catheter remains in place for several hours or days after surgery, and is attached to a pump so the patient can administer medication on demand.

In other cases, peripheral nerve blocks are used to limit sensation in specific regions of the body. By injecting local anesthetic near a nerve or nerve plexus that supplies the area where the surgery will be performed, all sensation is blunted and the affected area is numbed and feels "asleep." Some patients remain awake, but sedated, during surgery; others are given general anesthesia. Two important advantages to the use of peripheral nerve blocks in patients who are awake during surgery is the avoidance of the side effects of general anesthesia (nausea and vomiting) and complications that could occur during intubation, the placement of a tube in the patient's airway. The use of peripheral nerve blocks alone may be best suited to surgical procedures involving the arms, legs, and shoulders.

### *Pain management during surgery*

General anesthesia is the standard for pain management during surgery. Topical local anesthetics are also sometimes used to numb the surgical site before any incisions are made. This is the method used frequently with laparoscopic procedures. In a **laparoscopy**, the surgeon inserts a laparoscope (an instrument that has

a tiny video camera attached) through a small incision. Other small incisions are made into which the surgeon inserts **surgical instruments**, and in this way the surgeon repairs or removes diseased or damaged tissues. Local anesthetics minimize pain trauma to the surgical site and the central nervous system.

### *Post-surgery pain management*

In most hospitals during the past century, post-surgical pain management consisted only of the administration of **analgesics** and narcotics immediately after surgery. These drugs were usually given by intravenous or intramuscular injection, or by mouth. This is still the most common method for managing post-operative pain.

Management of these drugs, nevertheless, has variant applications. Some hospitals insist on a routine of scheduled medications, rather than giving medications as needed. The health care staff in these instances state that when patients take medications before the pain appears, the body does not over-react to the pain stimulus. Therefore, staying ahead of the pain is critical.

Other hospitals advocate continuous around-the-clock dosing through the use of a pump-type device that immediately delivers medication into the veins (intravenously, the most common method), under the skin (subcutaneously), or between the dura mater and the skull (epidurally). A health care provider programs the device with the specific dosage to deliver at each request made by the patient, as well as the total permitted during the time for which the device is set (commonly eight hours, sometimes 12, especially if the health care providers are working 12-hour shifts). Some of these devices are very sophisticated and even monitor themselves, ringing an alarm bell if there is an indication that they might be malfunctioning. The patient administers the dose by pushing a button, and is encouraged to keep a steady supply of medication within his or her system. This is called **patient-controlled analgesia (PCA)**.

PCA provides pain medication at the patient's need. However, because opium-like pain-relievers (opioids) are the medications these pumps deliver, there has been some concern about possible narcotic addiction. The pumps are calibrated to a maximum dosage, and are limited to a maximum dose every eight (or twelve) hours. The health care staff checks the equipment regularly, and records the number of times the patient pushed the pump button during the previous period. If the patient has pushed the button more times than allowed, the pump refuses to administer more medication. The patient should notify the

health care staff if a specific medication is ineffective. In some cases, the patient needs encouragement to use the pump more, if necessary.

Nonsteroid anti-inflammatory analgesics (NSAIDs) are best used for continuous around-the-clock pain relief. This prevents the extremes in pain perception that occur with on-demand dosing; sometimes the patient feels no pain and extreme pain at other times. Opioids are best given on a schedule or in a computerized pump, which can prevent overdoses.

Another method used post-surgically is the On-Q or the “pain relief ball.” It is a balloon-type device that administers non-narcotic medication to the incision site through a small catheter. When the incision site is closed, the catheter is attached to the surgical site and the balloon or pump is either taped to the patient’s skin, carried in a pocket or pouch, or attached to the patient’s clothing. The pump numbs the incision site by flooding it with anesthetic. Recent tests show that On-Q reduces narcotic use by 40% in cesarean patients, and eliminates all narcotics in 43% of hysterectomy patients.

#### *Alternative non-medical methods*

Some non-medical methods can help reduce post-operative pain. Patient education about the surgical procedure and the expected after-care necessary can help reduce stress, which can affect the perception of pain. Education, like visualization, prepares the mind for surgery and recovery. The patient knows what to expect, thereby removing fear of the unknown. Education also enlists the patient’s cooperation and may encourage a feeling of control and empowerment, which reduces stress, fear, and helplessness. These factors can contribute to less perceived pain. Therefore, both education and visualization can be helpful in minimizing pain perception and encouraging a positive attitude after surgery, which can promote healing.

Meditation and deep breathing techniques also can reduce stress. These techniques can lower blood pressure and increase oxygen levels, which are critical to a healthy recovery. Hypnosis before and after surgery may calm the mind and emotions, and mute the perception of pain.

#### *Multiple methods*

Multimodal analgesia uses more than one method of pain management. Multiple methods can actually reduce the amount of medications necessary to relieve pain, and can minimize uncomfortable side effects. Using presurgical, surgical, and post-surgical techniques allows the patient to come out of surgery with the pain already

under control. He or she does not have to experience the shock of intense pain at the incision site or elsewhere in the body. Some pain is probable; however, a patient should not be in intense pain after surgery. Pain management should occur before pain appears rather than in reaction to pain.

Further knowledge about multimodal pain management will be necessary as more outpatient and office-based surgery is done. Finding the right combination of methods for an individual patient is the challenge and responsibility of the health care team.

#### *Opioid-tolerant patients*

Of great concern to health-care professionals is how to provide post-operative pain management to patients who are opioid tolerant. These patients require higher and more frequent doses of narcotics for pain relief. They may also need to stay on the narcotics longer, and gradually step back down to their presurgery levels.

Patients who are opioid tolerant are not necessarily illegal drug users, but may be taking medications in combination with a narcotic, such as oxycodone/acetaminophen or acetaminophen/codeine. Patients who take opioid medications regularly may be treating pain for conditions like cancer, fibromyalgia, arthritis, or traumatic physical injuries.

It is important for anesthesiologists to aggressively treat pain for opioid-tolerant patients in the **recovery room**, where they can be closely monitored. Patient-controlled pain administration or continuous infusion, either in an IV or in an epidural catheter, has the best chance of controlling post-surgical pain together with the pain caused by preexisting conditions. When the patient is able to take medications orally, NSAIDs can supplement the use of opioid analgesia, sometimes reducing the total amount of opioids used. Newer, COX-2 inhibitors have proven effective in reducing pain without many of the side effects that NSAIDs possess (liver complications, kidney impairment, intestinal tract irritation, and bleeding), and seem to be a good fit for many opioid-tolerant patients.

#### **Preparation**

Before having any surgery, the patient should talk with the physician, surgeon, and if possible, the anesthesiologist in order to gain a full understanding of the procedure and what to expect immediately following surgery. It is important to develop a pain management plan with the health care team, and for the patient to be open about medication use, including opioids. Usually the patient will meet the anesthesiologist the day

of the surgery to discuss pain management options for the operation. Being informed about the surgical procedure and anesthesia options will give the patient an opportunity to ask questions and respond accurately to those asked by the anesthesiologist.

The physician should take a complete medical history, and order tests to determine the patient's current liver and kidney functions. The patient should not eat or drink before surgery. This helps minimize the side effects of general anesthesia and pain medications, such as nausea and vomiting. If the patient cannot reach a comfort level with the prescribed medication regime, he or she should discuss this with the health-care staff and physician.

### Normal results

After surgery, a patient should not have to endure severe pain. A reasonable comfort level can be reached in most cases. Prudent pain management will allow the patient to eat, sleep, move, and begin doing normal activities even while in the hospital, and especially when returning home. Recovery may take several weeks after surgery; however, the patient should be made comfortable as possible with a regime of oral pain medications.

### Risks

Pain medications may have unpleasant side effects. In many people, narcotics cause nausea, vomiting, and impaired mental functioning. NSAIDs can cause kidney failure, intestinal bleeding, and liver dysfunction, although these side-effects are not common with short-term use. The NSAID ketorolac has been associated with acute renal (kidney) failure even when given for minor oral surgery in an outpatient setting. Early screening for kidney problems and close monitoring for kidney failure or dehydration can prevent most of these problems.

There are adequate safeguards in place, especially in patient-controlled analgesic pumps, to prevent addiction to narcotics; however, some patients do become addicted.

## Postoperative care

### Definition

Postoperative care is the management of a patient after surgery. This includes care given during the immediate postoperative period, both in the **operating room** and postanesthesia care unit (PACU), as well as during the days following surgery.

### Purpose

The goal of postoperative care is to prevent complications such as infection, to promote healing of the surgical incision, and to return the patient to a state of health.

### Description

Postoperative care involves assessment, diagnosis, planning, intervention, and outcome evaluation. The extent of postoperative care required depends on the individual's presurgical health status, type of surgery, and whether the surgery was performed in a day-surgery setting or in the hospital. Patients who have procedures done in a day-surgery center usually require only a few hours of care by health care professionals before they are discharged to go home. If postanesthesia or postoperative complications occur within these hours, the patient must be admitted to the hospital. Patients who are admitted to the hospital

may require days or weeks of postoperative care by hospital staff before they are discharged.

### *Postanesthesia care unit (PACU)*

The patient is transferred to the PACU after the surgical procedure, anesthesia reversal, and extubation (if it was necessary). The amount of time the patient spends in the PACU depends on the length of surgery, type of surgery, status of regional anesthesia (e.g., spinal anesthesia), and the patient's level of consciousness. Rather than being sent to the PACU, some patients may be transferred directly to the critical care unit. For example, patients who have had coronary artery bypass grafting are sent directly to the critical care unit.

In the PACU, the anesthesiologist or the nurse anesthetist reports on the patient's condition, type of surgery performed, type of anesthesia given, estimated blood loss, and total input of fluids and output of urine during surgery. The PACU nurse should also be made aware of any complications during surgery, including variations in hemodynamic (blood circulation) stability.

Assessment of the patient's airway patency (openness of the airway), **vital signs**, and level of consciousness are the first priorities upon admission to the PACU. The following is a list of other assessment categories:

- surgical site (intact dressings with no signs of overt bleeding)
- patency (proper opening) of drainage tubes/drains
- body temperature (hypothermia/hyperthermia)
- patency/rate of intravenous (IV) fluids
- circulation/sensation in extremities after vascular or orthopedic surgery
- level of sensation after regional anesthesia
- pain status
- nausea/vomiting

The patient is discharged from the PACU when he or she meets established criteria for discharge, as determined by a scale. One example is the Aldrete scale, which scores the patient's mobility, respiratory status, circulation, consciousness, and pulse oximetry. Depending on the type of surgery and the patient's condition, the patient may be admitted to either a general surgical floor or the **intensive care unit**. Since the patient may still be sedated from anesthesia, safety is a primary goal. The patient's call light should be in the hand and side rails up. Patients in a day surgery setting are either discharged from the PACU to the unit, or are directly discharged home after they

## KEY TERMS

**Ambulate**—To move from place to place (walk).

**Auscultation**—The act of listening to sounds arising within organs as an aid to diagnosis and treatment.

**Catheter**—A tubular medical device inserted into canals, vessels, passageways, or body cavities to permit injection or withdrawal of fluids, or to keep a passage open.

**Deep vein thrombosis**—Potentially life-threatening blood clot in one of the deep veins of the body, and often in the legs secondary to immobility after surgery. Symptoms include pain, warmth, swelling, and redness.

**Dehiscence**—Separation of a surgical incision or rupture of a wound closure.

**Ileus**—Obstruction in or immobility of the intestines. Symptoms include nausea and vomiting, absent bowel sounds, abdominal pain, and abdominal distension.

**Incentive spirometer**—Device that is used postoperatively to prevent lung collapse and promote maximum inspiration. The patient inhales until a preset volume is reached, then sustains the volume by holding his or her breath for three to five seconds.

**Oximetry**—Measuring the degree of oxygen saturation of circulating blood.

**PACU**—The postanesthesia care unit, where the patient is cared for after surgery.

**Patency**—The quality or state of being open or unobstructed.

**Patient-controlled analgesia pump**—A pump that the patient uses to self-administer medication to control pain.

**Pulmonary embolism**—Potentially life-threatening blockage of a pulmonary artery by fat, air, or a blood clot that originated elsewhere in the body. Symptoms include acute shortness of breath and sudden chest pain.

have urinated, gotten out of bed, and tolerated a small amount of oral intake.

### *First 24 hours*

After the hospitalized patient transfers from the PACU, the nurse taking over his or her care should assess the patient again, using the same previously mentioned categories. If the patient reports "hearing" or

feeling pain during surgery (under anesthesia) the observation should not be discounted. The anesthesiologist or nurse anesthetist should discuss the possibility of an episode of awareness under anesthesia with the patient. Vital signs, respiratory status, pain status, the incision, and any drainage tubes should be monitored every one to two hours for at least the first eight hours.

**Body temperature** must be monitored, since patients are often hypothermic after surgery, and may need a warming blanket or warmed IV fluids. Respiratory status should be assessed frequently, including assessment of lung sounds (auscultation) and chest excursion, and presence of an adequate cough. Fluid intake and urine output should be monitored every one to two hours. If the patient does not have a urinary catheter, the bladder should be assessed for distension, and the patient monitored for inability to urinate. The physician should be notified if the patient has not urinated six to eight hours after surgery. If the patient had a vascular or neurological procedure performed, circulatory status or neurological status should be assessed as ordered by the surgeon, usually every one to two hours. The patient may require medication for nausea or vomiting, as well as pain.

Patients with a **patient-controlled analgesia** pump may need to be reminded how to use it. If the patient is too sedated immediately after the surgery, the nurse may push the button to deliver pain medication. The patient should be asked to rate his or her pain level on a pain scale in order to determine his or her acceptable level of pain. Controlling pain is crucial so that the patient may perform coughing, deep breathing exercises, and may be able to turn in bed, sit up, and, eventually, walk.

Effective preoperative teaching has a positive impact on the first 24 hours after surgery. If patients understand that they must perform respiratory exercises to prevent pneumonia; and that movement is imperative for preventing blood clots, encouraging circulation to the extremities, and keeping the lungs clear; they will be much more likely to perform these tasks. Understanding the need for movement and respiratory exercises also underscores the importance of keeping pain under control. Respiratory exercises (coughing, deep breathing, and incentive spirometry) should be done every two hours. The patient should be turned every two hours, and should at least be sitting on the edge of the bed by eight hours after surgery, unless contraindicated (e.g., after **hip replacement**). Patients who are not able to sit up in bed due to their surgery will have sequential compression devices on their legs until they are able to move about. These are stockings that inflate with air in order to simulate the effect of walking on the calf

muscles, and return blood to the heart. The patient should be encouraged to splint any chest and abdominal incisions with a pillow to decrease the pain caused by coughing and moving. Patients should be kept NPO (nothing by mouth) if ordered by the surgeon, at least until their cough and gag reflexes have returned. Patients often have a dry mouth following surgery, which can be relieved with oral sponges dipped in ice water or lemon ginger mouth swabs.

Patients who are discharged home after a day surgery procedure are given prescriptions for their pain medications, and are responsible for their own pain control and respiratory exercises. Their families (or caregivers) should be included in preoperative teaching so that they can assist the patient at home. The patient should be reminded to call his or her physician if any complications or uncontrolled pain arise. These patients are often managed at home on a follow-up basis by a hospital-connected visiting nurse or **home care** service.

### *After 24 hours*

After the initial 24 hours, vital signs can be monitored every four to eight hours if the patient is stable. The incision and dressing should be monitored for the amount of drainage and signs of infection. The surgeon may order a dressing change during the first postoperative day; this should be done using sterile technique. For home-care patients this technique must be emphasized.

The hospitalized patient should be sitting up in a chair at the bedside and ambulating (walking) with assistance by this time. Respiratory exercises are still be performed every two hours, and incentive spirometry values should improve. Bowel sounds are monitored, and the patient's diet gradually increased as tolerated, depending on the type of surgery and the physician's orders.

The patient should be monitored for any evidence of potential complications, such as leg edema, redness, and pain (deep vein thrombosis), shortness of breath (pulmonary embolism), dehiscence (separation) of the incision, or ileus (intestinal obstruction). The surgeon should be notified immediately if any of these occur. If dehiscence occurs, sterile saline-soaked dressing packs should be placed on the wound.

### **Preparation**

Patients receive a great deal of information on postoperative care. They may be offered pain medication in preparation for any procedure that is likely to cause discomfort. Patients may receive educational

materials such as handouts and video tapes, so that they will have a clear understanding of what to expect postoperatively.

### Aftercare

Aftercare includes ensuring that patients are comfortable, either in bed or chair, and that they have their call lights accessible. After dressing changes, blood-soaked **dressings** should be properly disposed of in a biohazard container. Pain medication should be offered before any procedure that might cause discomfort. Patients should be given the opportunity to ask questions. In some cases, they may ask the nurse to demonstrate certain techniques so that they can perform them properly once they return home.

### Normal results

The goal of postoperative care is to ensure that patients have good outcomes after surgical procedures. A good outcome includes recovery without complications and adequate **pain management**. Another objective of postoperative care is to assist patients in taking responsibility for regaining optimum health.

## Power of attorney

### Definition

Power of attorney, also known as durable medical power of attorney, is a legal mechanism that empowers a designated person to make medical decisions for a patient should the patient be unable to make the decisions due to incapacitation.

### Purpose

Power of attorney assures that a patient's wishes are acknowledged in the medical setting. Along with other legal documents such as a **living will** and a **do not resuscitate (DNR) order**, the power of attorney designates the agent or person who is legally authorized to act for the patient in the medical setting. All three mechanisms are a part of what is known as advanced medical directives. The purpose of advanced directives is to have the patient's wishes for medical care carried out even when the patient is incapacitated and can no longer make his or her wishes known.

### Description

The patient's agent is the person appointed by the patient to represent him or her in medical situations where decisions must be made. This surrogate, through the power of attorney authorization, has all of the rights that the patient has with respect to deciding on medical procedures. These include the rights to refuse treatment, to agree to treatment, or to have treatment withdrawn.

Guided by a living will, which is a document developed in advance that reflects the patient's wishes, the agent acts on behalf of the patient with providers, administrators, and other legal agents. In most states, surrogates can act for the patient on any medical procedure, including a decision to refuse life support procedures such as resuscitation. States differ, however, on whether health agents can invoke a **DNR order**.

In the difficult times that families experience with a seriously ill or terminally ill family member, health agents play a major role in making decisions and stipulating what the patient's wishes are with respect to his or her treatment or palliative care needs. Health agents can work with or without a living will. The crucial feature of the power of attorney is that it empowers the patient's agent to respond to changes in the patient's health and to make flexible decisions. It is the health agent, rather than the patient, who must be apprised of all medical options, weigh the risk and benefits, and make a decision based on the specific situation.

## KEY TERMS

**Advanced medical directives**—Documents prepared in advance of medical care that reflect the wishes of patients for or against medical procedures should they become incapacitated.

**Health care agent**—Also known as the surrogate or patient representative, this is the person who has power of attorney to have the patient's wishes carried out if the patient is incapacitated.

**Living will**—A document that is usually included in advanced medical directives containing explicit medical procedures that patients' wishes to have or to refuse should they become incapacitated.

## Preparation

The person who has the medical power of attorney for a patient is only as good as his or her level of understanding of the patient and level of respect for the patient's wishes. There are some specific steps that can be taken to prepare the health care agent for power of attorney responsibilities. These steps include:

- The patient must think about medical treatments he or she would or would not like to have in different medical situations such as accidents, acute and life-threatening injuries, nursing home care, etc.
- If possible, the patient should write down his or her medical wishes and have these developed into a living will.
- The patient will want to convey these medical wishes to family and friends, as well as the identity of the person who will have power of attorney.
- Whether a written document is drafted or not, it is important that the patient have discussions with the designated agent so that his or her wishes can be carried out if the need arises. Not all elements of the medical decisions required can be known in advance. Hence, it is very important that the health agent knows the patient, knows the patient's wishes and rationale, and understands fully what is of value to the patient. Family and health providers should also be informed of the patient's wishes.

Medical decisions likely to be faced in severe health emergencies include options for **cardiopulmonary resuscitation** (CPR), diagnostic tests, administration of drugs, surgery, the use of life-supporting technologies, and organ and tissue use. However, there are also other decisions that can may require decisions from the agent. These may include family

members, and how much say they will have in decision making, issues of visitation, and other issues only somewhat related to the medical care. It is important that the agent understand and honor the wishes of the patient in all of these areas.

Once the initial steps for the advanced instructions are in place, an official medical power of attorney form for the state of residence or health care must be filled out. These may be two different states. It is important to have a medical power of attorney for any and all states in which medical care might be provided.

## Normal results

All medical directives, whether the living will, power of attorney, or **do not resuscitate order**, are respected by all health personnel in whatever medical setting the chosen state stipulates. These generally include hospitals, emergency rooms, emergency vehicles, and short- or long-term care facilities such as **hospice** care. Many states also include the home. The medical directives become a part of the patient's medical record and must be honored by any and all health personnel involved in the patient's treatment or care.

## Preoperative care

### Definition

Preoperative care is the preparation and management of a patient prior to surgery. It includes both physical and psychological preparation.

### Purpose

Patients who are physically and psychologically prepared for surgery tend to have better surgical outcomes. Preoperative teaching meets the patient's need for information regarding the surgical experience, which in turn may alleviate most of his or her fears. Patients who are more knowledgeable about what to expect after surgery, and who have an opportunity to express their goals and opinions, often cope better with postoperative pain and decreased mobility. Preoperative care is extremely important prior to any invasive procedure, regardless of whether the procedure is minimally invasive or a form of major surgery.

Preoperative teaching must be individualized for each patient. Some people want as much information as possible, while others prefer only minimal information because too much knowledge may increase their anxiety. Patients have different abilities to comprehend medical procedures; some prefer printed information, while others learn more from oral presentations. It is important for the patient to ask questions during preoperative teaching sessions.

### Description

Preoperative care involves many components, and may be done the day before surgery in the hospital, or during the weeks before surgery on an outpatient basis. Many surgical procedures are now performed in a day surgery setting, and the patient is never admitted to the hospital.

#### *Physical preparation*

Physical preparation may consist of a complete medical history and physical exam, including the patient's surgical and anesthesia background. The patient should inform the physician and hospital staff if he or she has ever had an adverse reaction to anesthesia (such as anaphylactic shock), or if there is a family history of malignant hyperthermia. Laboratory tests may include **complete blood count**, electrolytes, **prothrombin time**, activated **partial thromboplastin time**, and **urinalysis**. The patient will most likely have an **electrocardiogram (EKG)** if he or she has a history of cardiac disease, or is over 50 years of age. A

## KEY TERMS

**Activated partial thromboplastin time (APTT)**—A lab test that detects coagulation defects in the intrinsic clotting cascade. Used to regulate heparin dosing.

**Ambulate**—Move from place to place (walk).

**Anaphylactic shock**—A systemic reaction that is often severe and occasionally fatal due to a second exposure to a specific antigen (i.e., wasp venom or penicillin) after previous sensitization that results in symptoms (particularly respiratory symptoms, fainting, itching, and hives).

**Anesthesia**—A safe and effective means of alleviating pain during a medical procedure.

**Complete blood count (CBC)**—A lab test that determines the number of red and white blood cells per cubic millimeter of blood.

**Electrocardiogram (EKG)**—A graphic record showing the electrical activity of the heart.

**Incentive spirometer**—Device that is used postoperatively to prevent lung collapse and promote maximum inspiration. The patient inhales until a preset volume is reached, then sustains the volume by holding the breath for three to five seconds.

**Patient-controlled analgesia pump**—A pump that the patient uses to self-administer medication to control pain.

**Prothrombin time (PT)**—A lab test that detects coagulation defects in the extrinsic clotting cascade. Used to regulate coumadin dosing.

**chest x ray** is done if the patient has a history of respiratory disease. Part of the preparation includes assessment for risk factors that might impair healing, such as nutritional deficiencies, steroid use, radiation or chemotherapy, drug or alcohol abuse, or metabolic diseases such as diabetes. The patient should also provide a list of all medications, vitamins, and herbal or food supplements that he or she uses. Supplements are often overlooked, but may cause adverse effects when used with general anesthetics (e.g., St. John's wort, valerian root). Some supplements can prolong bleeding time (e.g., garlic, ginkgo biloba).

Latex allergy has become a public health concern. Latex is found in most sterile surgical gloves, and is a common component in other medical supplies including **general anesthesia** masks, tubing, and multi-dose medication vials. It is estimated that 1–6% of the

general population and 8–17% of health care workers have this allergy. Children with disabilities are particularly susceptible. This includes children with spina bifida, congenital urological abnormalities, cerebral palsy, and Dandy-Walker syndrome. At least 50% of children with spina bifida are latex-sensitive as a result of early, frequent surgical exposure. There is currently no cure available for latex allergy, and research has found that the allergy accounts for up to 19% of all anaphylactic reactions during surgery. The best treatment is prevention, but immediate symptomatic treatment is required if the allergic response occurs. Every patient should be assessed for a potential latex reaction. Patients with latex sensitivity should have their chart flagged with a caution label. Latex-free gloves and supplies must be used for anyone with a documented latex allergy.

Bowel clearance may be ordered if the patient is having surgery of the lower gastrointestinal tract. The patient should start the bowel preparation early the evening before surgery to prevent interrupted sleep during the night. Some patients may benefit from a sleeping pill the night before surgery.

The night before surgery, skin preparation is often ordered, which can take the form of scrubbing with a special soap (i.e., Hibiclens), or possibly hair removal from the surgical area. Shaving hair is no longer recommended because studies show that this practice may increase the chance of infection. Instead, adhesive barrier drapes can contain hair growth on the skin around the incision.

### *Psychological preparation*

Patients are often fearful or anxious about having surgery. It is often helpful for them to express their concerns to health care workers. This can be especially beneficial for patients who are critically ill, or who are having a high-risk procedure. The family needs to be included in psychological preoperative care. Pastoral care is usually offered in the hospital. If the patient has a fear of **dying** during surgery, this concern should be expressed, and the surgeon notified. In some cases, the procedure may be postponed until the patient feels more secure.

Children may be especially fearful. They should be allowed to have a parent with them as much as possible, as long as the parent is not demonstrably fearful and contributing to the child's apprehension. Children should be encouraged to bring a favorite toy or blanket to the hospital on the day of surgery.

Patients and families who are prepared psychologically tend to cope better with the patient's postoperative

course. Preparation leads to superior outcomes since the goals of recovery are known ahead of time, and the patient is able to manage postoperative pain more effectively.

### *Informed consent*

The patient's or guardian's written consent for the surgery is a vital portion of preoperative care. By law, the physician who will perform the procedure must explain the risks and benefits of the surgery, along with other treatment options. However, the nurse is often the person who actually witnesses the patient's signature on the consent form. It is important that the patient understands everything he or she has been told. Sometimes, patients are asked to explain what they were told so that the health care professional can determine how much is understood.

Patients who are mentally impaired, heavily sedated, or critically ill are not considered legally able to give consent. In this situation, the next of kin (spouse, adult child, adult sibling, or person with medical **power of attorney**) may act as a surrogate and sign the consent form. Children under age 18 must have a parent or guardian sign.

### *Preoperative teaching*

Preoperative teaching includes instruction about the preoperative period, the surgery itself, and the postoperative period.

Instruction about the preoperative period deals primarily with the arrival time, where the patient should go on the day of surgery, and how to prepare for surgery. For example, patients should be told how long they should be NPO (nothing by mouth), which medications to take prior to surgery, and the medications that should be brought with them (such as inhalers for patients with asthma).

Instruction about the surgery itself includes informing the patient about what will be done during the surgery, and how long the procedure is expected to take. The patient should be told where the incision will be. Children having surgery should be allowed to "practice" on a doll or stuffed animal. It may be helpful to demonstrate procedures on the doll prior to performing them on the child. It is also important for family members (or other concerned parties) to know where to wait during surgery, when they can expect progress information, and how long it will be before they can see the patient.

Knowledge about what to expect during the postoperative period is one of the best ways to improve the patient's outcome. Instruction about expected activities

can also increase compliance and help prevent complications. This includes the opportunity for the patient to practice coughing and deep breathing exercises, use an incentive spirometer, and practice splinting the incision. Additionally, the patient should be informed about early ambulation (getting out of bed). The patient should also be taught that the respiratory interventions decrease the occurrence of pneumonia, and that early leg exercises and ambulation decrease the risk of blood clots.

Patients hospitalized postoperatively should be informed about the tubes and equipment that they will have. These may include multiple intravenous lines, drainage tubes, **dressings**, and monitoring devices. In addition, they may have sequential compression stockings on their legs to prevent blood clots until they start ambulating.

**Pain management** is the primary concern for many patients having surgery. Preoperative instruction should include information about the pain management method that they will utilize postoperatively. Patients should be encouraged to ask for or take pain medication before the pain becomes unbearable, and should be taught how to rate their discomfort on a pain scale. This instruction allows the patients, and others who may be assessing them, to evaluate the pain consistently. If they will be using a **patient-controlled analgesia** pump, instruction should take place during the preoperative period. Use of alternative methods of pain control (distraction, imagery, positioning, mindfulness meditation, music therapy) may also be presented.

Finally, the patient should understand long-term goals such as when he or she will be able to eat solid food, go home, drive a car, and return to work.

### Preparation

It is important to allow adequate time for preparation prior to surgery. The patient should understand that he or she has the right to add or strike out items on the generic consent form that do not pertain to the specific surgery. For example, a patient who is about to undergo a **tonsillectomy** might choose to strike out (and initial) an item that indicates sterility might be a complication of the operation.

### Normal results

The anticipated outcome of preoperative care is a patient who is informed about the surgical course, and copes with it successfully. The goal is to decrease complications and promote recovery.

## Preparing for surgery

### Definition

Preparing for a planned surgery (also called **elective surgery**) includes selecting a surgery center and surgeon to perform the procedure, scheduling the surgery, undergoing **presurgical testing**, meeting with health-care professionals and the **surgical team**, receiving education about the procedure, receiving and following all of the appropriate preoperative instructions, and signing a consent form.

### Purpose

Preparing for surgery helps the patient understand what to expect before surgery and ensures the patient is physically and psychologically ready for the surgery.

### Description

Most patients go to the surgery center or hospital the same day as the scheduled surgery; thus, many of the steps involved in preparing for surgery will take place from one to four weeks before the scheduled surgery. Many surgeries are performed on an outpatient basis, which means that the patient goes home the same day as the surgery.

### Selecting a surgeon and surgery center

**SURGEON.** A surgeon, along with a multi-disciplinary team of surgical specialists, will perform the surgery.

The surgeon should be board certified by the American Board of Surgery, as well as certified by the medical specialty board or boards related to the type of surgery performed. Certification from a medical specialty board means that the surgeon has completed an approved educational training program (including three to seven years of full-time training in an accredited residency program). Certification also includes an evaluation, including an examination that assessed the surgeon's knowledge, skills, and experience necessary to perform high-quality patient care in that specialty.

There are 24 certifying boards recognized by the American Board of Member Specialties (ABMS) and the American Medical Association (AMA). Most of the ABMS boards issue time-limited certificates, valid for six to 10 years. This requires physicians to become re-certified to maintain their board certification—a process that includes a credential review, continuing education in the specialty, and additional examinations. Even though board certification is not required for an individual physician to practice medicine, most hospitals require that a certain percentage of their staff be board certified.

The letters FACS (Fellow of the American College of Surgeons) after a surgeon's name are a further indication of a surgeon's qualifications. Those who become Fellows of the American College of Surgeons have passed a comprehensive evaluation of their **surgical training** and skills; they also have demonstrated their commitment to high standards of ethical conduct. This evaluation is conducted according to national standards that were established to ensure that patients receive the best possible surgical care.

A surgeon's membership in professional societies is also an important consideration. Professional societies provide an independent forum for medical specialists to discuss issues of national interest and mutual concern. Examples of professional societies include the Society of Thoracic Surgeons (STS) and the American College of Physicians—American Society of Internal Medicine (ACP-ASIM).

To find information about a surgeon's qualifications, the patient can call a state or county medical association for assistance. A reference book is also available: *The Official ABMS Directory of Board Certified Medical Specialists* that lists all surgeons who are certified by approved boards. This publication also contains brief information about each surgeon's medical education and training, and it can be found in many libraries.

**SURGERY CENTER.** The surgeon will arrange for the procedure to be performed in a hospital where he or

## KEY TERMS

**Case manager**—A health-care professional who can provide assistance with a patient's needs beyond the hospital.

**Discharge planner**—A health-care professional who helps patients arrange for health and home care needs after they go home from the hospital.

**Electrocardiogram (ECG, EKG)**—A test that records the electrical activity of the heart using small electrode patches attached to the skin on the chest.

**Infectious disease team**—A team of physicians who help control the hospital environment to protect patients against harmful sources of infection.

**Informed consent**—An educational process between health-care providers and patients intended to instruct the patient about the nature and purpose of the procedure or treatment, the risks and benefits of the procedure, and alternatives, including the option of not proceeding with the test or treatment.

**Inpatient surgery**—Surgery that requires an overnight stay of one or more days in the hospital.

**NPO**—A term that means nothing by mouth. NPO refers to the time after which the patient is not allowed to eat or drink prior to a procedure or treatment.

**Outpatient surgery**—Also called same-day or ambulatory surgery. The patient arrives for surgery and returns home on the same day.

she has staff privileges. The patient should make sure the hospital has been accredited by the Joint Commission on Accreditation of Healthcare Organizations, a professionally sponsored program that stimulates a high quality of patient care in health-care facilities. Joint Commission accreditation means the hospital voluntarily sought accreditation and met national health and safety standards. There is also an accreditation option that is available for **ambulatory surgery centers**.

Selecting a surgery center that has a multidisciplinary team of specialists is important. The surgery team should include surgeons, infectious disease specialists, pharmacologists, and advanced care registered nurses. Other surgical team members may include fellows and residents, clinical coordinators, physical therapists, respiratory therapists, registered dietitians, social workers, and financial counselors.

Choosing a surgery center with experience is important. Some questions to consider when choosing a surgery center or hospital include:

- How many surgeries are performed annually and what are the outcomes/survival rates of those surgeries?
- How do the surgery center's outcomes compare with the national average?
- Does the surgery center offer treatment for a patient's specific condition? How experienced is the staff in treating that condition?
- What is the center's success record in providing the specific medical treatment or procedure?
- Does the surgery center have experience treating patients the same age as the inquiring patient?
- Does the surgery center explain the patient's rights and responsibilities?
- Does the surgery center have a written description of its services and fees?
- How much does the patient's type of treatment cost at this surgery center?
- Is financial help available?
- Who will be responsible for the patient's specific care plan while he or she is in the hospital?
- If the center is far from the patient's home, will accommodations be provided for caregivers?
- What type of services are available during the patient's hospital stay?
- Will a discharge plan be developed before the patient goes home from the hospital?
- Does the hospital provide training to help the patient care for his or her condition at home?

### *Scheduling the surgery*

Depending on the nature of the surgery, it may be scheduled within days or weeks after the surgery is determined to be the appropriate treatment option for the patient. The patient's surgery time may not be determined until the business day before the scheduled surgery. The patient may be instructed to call the surgical center to find out the time of the scheduled surgery.

The time the patient is told to report to the surgery center (arrival time) is not the time when the surgery will take place. Patients are told to arrive at the surgery center far enough in advance (usually about two hours prior to the scheduled surgery time) so they can be properly prepared for surgery. In some cases, the patient's surgery may need to be rescheduled if another patient requires **emergency surgery** at the patient's scheduled time.

The patient should ask the health-care providers if the scheduled surgery will be performed on an outpatient or inpatient basis. Outpatient means the patient goes home the same day as the surgery; inpatient means a hospital stay is required.

### *Presurgical testing*

Presurgical testing, also called preoperative testing or surgical consultation, includes a review of the patient's medical history, a complete **physical examination**, a variety of tests, patient education, and meetings with the health-care team. The review of the patient's medical history includes an evaluation of the patient's previous and current medical conditions, surgeries and procedures, medications, and any other health conditions such as allergies that may impact the surgery. Presurgical testing is generally scheduled within one week before the surgery.

The patient may find it helpful to bring along a family member or friend to the presurgical testing appointments. This caregiver can help the patient remember important details to prepare for surgery.

After attending the surgical consultation, the patient may desire to seek a **second opinion** to confirm the first doctor's treatment recommendations. The patient should check with his or her insurance provider to determine if the second opinion consultation is covered.

### *Meeting with the surgical team*

During the surgical consultation, the patient meets with the surgeon or a member of the surgeon's health-care team to discuss the surgery and other potential treatment options for the patient's medical condition. At some time before the surgery, the patient will meet with other health-care providers, including the anesthesiologist, nurse clinicians, and sometimes a dietitian, social worker, or rehabilitation specialist.

### *Patient education*

The surgical team will ensure that the patient understands the potential benefits and risks of the procedure as well as what to expect before the procedure and during the recovery. Patient education may include one-on-one instruction from a health-care provider, educational sessions in a group setting, or self-guided learning videos or modules. Informative and instructional handouts are usually provided to explain specific presurgical requirements.

Some surgery centers offer services such as guided imagery and relaxation tapes, massage therapy, aromatherapy, or other complementary techniques to reduce a patient's level of stress and anxiety before a

surgical procedure. Guided imagery is a form of focused relaxation that coaches the patient to visualize calm, peaceful images. Several research studies have proven that guided imagery can significantly reduce stress and anxiety before and after surgical and medical procedures and help the patient recover more rapidly. Guided imagery and relaxation tapes are available at many major bookstores and from some surgery centers. The patient may be able to listen to the tapes during the procedure, depending on the type of procedure being performed.

### *Preoperative instructions*

Preoperative instructions include information about reserving blood products for surgery, taking or discontinuing medications before the surgery, eating and drinking before surgery, quitting smoking, limiting activities before surgery, and preparing items to bring to the hospital the day of surgery.

### **BLOOD TRANSFUSIONS AND BLOOD DONATION.**

Blood transfusions may be necessary during surgery. A blood **transfusion** is the delivery of whole blood or blood components to replace blood lost through trauma, surgery, or disease. About one in three hospitalized patients will require a blood transfusion. The surgeon can provide an estimate of how much blood the patient's procedure may require.

To decrease the risk of infection and immunologic complications, some surgery centers offer a preoperative **blood donation** program. Autologous blood (from the patient) is the safest blood available for transfusion, since there is no risk of disease transmission. Methods of autologous donation or collection include:

- Intraoperative blood collection: the blood lost during surgery is processed, and the red blood cells are re-infused during or immediately after surgery.
- Preoperative donation: the patient donates blood once a week for one to three weeks before surgery. The blood is separated and the blood components needed are re-infused during surgery.
- Immediate preoperative hemodilution: the patient donates blood immediately before surgery to decrease the loss of red blood cells during surgery. Immediately after donating, the patient receives fluids to compensate for the amount of blood removed. Since the blood is diluted, fewer red blood cells are lost from bleeding during surgery.
- Postoperative blood collection: blood lost from the surgical site right after surgery is collected and re-infused after the surgical site has been closed.

The surgeon determines what type of blood collection process, if any, is appropriate.

**MEDICATION GUIDELINES.** Depending on the type of surgery scheduled, certain medications may be prescribed or restricted before the surgery. The health-care team will provide specific guidelines. If certain medications need to be restricted before surgery, the patient will receive a complete list of the medications (including prescription, over-the-counter, and herbal medications) to avoid taking before the scheduled surgery.

If the physician advises the patient to take prescribed medication within 12 hours before surgery, it should be taken with small sips of water.

The patient should not bring any medications to the hospital; all necessary medications, as ordered by the doctor, will be provided in the hospital.

**EATING AND DRINKING BEFORE SURGERY.** Before most surgeries, the patient is advised not to eat or drink anything after midnight the evening before the surgery. This includes no smoking and no gum chewing. The patient should not drink any alcoholic beverages for at least 24 hours before surgery, unless instructed otherwise. If the patient has diabetes or if the surgery is to be performed on a child, the patient should ask the health-care team for specific guidelines about eating and drinking before surgery.

### *Smoking cessation*

Patients who will undergo any surgical procedure are encouraged to quit smoking and stop using tobacco products at least two weeks before the procedure, and to make a commitment to be a nonsmoker after the procedure. Ideally, the patient should quit smoking at least eight weeks prior to surgery. Quitting smoking before surgery helps the patient recover more quickly from surgery. There are several **smoking cessation** programs available in the community. The patient should ask a health-care provider for more information if he or she needs help quitting smoking.

### *Activity before surgery*

The patient should eat right, rest, and **exercise** as normal before surgery, unless given other instructions. The patient should try to get enough sleep to build up energy for the surgery. The health-care team may advise the patient to scrub the planned surgical site with a special disinfecting soap the evening before the surgery.

**MAKING PLANS FOR HOME AND WORK.** The patient should make arrangements ahead of time for someone to care for children and take care of any other necessary activities at home such as getting the mail or newspapers. The patient should inform family members about the scheduled surgery in advance, so they can provide help and support before, during, and after surgery.

The patient should ask the health-care team what supplies may be needed after surgery during **recovery at home** so these items can be purchased or rented ahead of time. Some supplies that may be needed include an adaptive chair for the toilet or bathtub, or supplies for changing the wound dressing at home. Ask the health care providers if **home care** assistance (in which a visiting nurse visits the home to provide medical care) will be needed after surgery.

### *Items to bring to the hospital*

The patient should bring a list of current medications, allergies, and appropriate medical records upon admission to the surgery center. The patient should also bring a prepared list of questions to ask.

The patient should not bring valuables such as jewelry, credit cards or other items. A small amount of cash (no more than \$20) may be packed to purchase items such as newspapers or magazines.

Women should not wear nail polish or makeup the day of surgery.

If a hospital stay is expected after surgery, the patient should only pack what is needed. Some essential items include a toothbrush, toothpaste, comb or brush, deodorant, razor, eyeglasses (if applicable), slippers, robe, pajamas, and one change of comfortable clothes to wear when going home. The patient should also bring a list of family members' names and phone numbers to contact in an emergency.

### *Transportation*

The patient should arrange for transportation home, since the effects of anesthesia and other medications given before surgery make it unsafe to drive.

### *Preoperative preparation*

Upon arriving at the hospital or surgery center, the patient will be required to complete paperwork and show an insurance identification card, if insured. An identification bracelet that includes the patient's name and doctor's name will be placed on the patient's wrist.

**INFORMED CONSENT.** The health-care provider will review the **informed consent** form and ask the patient to sign it. Informed consent is an educational process between health-care providers and patients. Before any procedure is performed, the patient is asked to sign a consent form. Before signing the form, the patient should understand the nature and purpose of the procedure or treatment, the risks and benefits of the procedure, and alternatives, including the option of not proceeding with the procedure. Signing the informed

consent form indicates that the patient permits the surgery or procedure to be performed. During the discussion about the procedure, the health-care providers are available to answer the patient's questions about the consent form or procedure.

**ADVANCED DIRECTIVES.** The health-care provider will ask the patient if he or she has any advance directives to be included in the patient's file. Advance directives are legal documents that increase a patient's control over medical decisions. A patient may decide medical treatment in advance, in the event that he or she becomes physically or mentally unable to communicate his or her wishes. Advance directives either state what kind of treatment the patient wants to receive (**living will**), or authorize another person to make medical decisions for the patient when he or she is unable to do so (durable **power of attorney**). Advance directives are not required and may be changed or canceled at any time. Any change should be written, signed and dated in accordance with state law, and copies should be given to the physician and to others who received original copies. Advance directives can be revoked either in writing or by destroying the document. Advance directives are not do-not-resuscitate (DNR) orders. A **DNR order** indicates that a person—usually with a terminal illness or other serious medical condition—has decided not to have **cardiopulmonary resuscitation** (CPR) performed in the event that his or her heart or breathing stops.

**TESTS AND PREOPERATIVE EVALUATION.** Some routine tests will be performed, including blood pressure, temperature, pulse, and weight checks; blood tests; **urinalysis**; **chest x ray**; and **electrocardiogram** (ECG). A brief physical exam will be performed. In some cases, an enema may be required. The health-care team will ask several questions to evaluate the patient's condition and to complete the final preparations for surgery. The patient should inform the health-care team if he or she drinks alcohol on a daily basis so precautions can be taken to avoid complications during and after surgery.

**FINAL SURGICAL PREPARATION.** Preoperative preparation generally includes these steps:

- The patient changes into a hospital gown.
- The patient removes (as applicable) contact lenses and glasses, dentures, hearing aids, nail polish, and jewelry.
- The patient empties his or her bladder.
- The health-care providers clean and possibly shave the area on the body where the surgery will be performed.
- The patient may receive medication to aid relaxation.

- An intravenous catheter will be placed in a vein in the patient's arm to deliver fluids, medications, or blood during surgery.
- In some hospitals, the patient may wait in an area called a holding area until the operating room and surgical team are ready. Depending on the hospital's policy, one or two of the patient's family members may wait with the patient.
- The patient is taken to the operating room in a wheelchair or on a bed (also called a gurney) where monitors are placed to evaluate the patient's condition during surgery.
- Anesthesia is administered; the type of anesthesia administered will depend upon the procedure, the patient's general health, and medications.
- A catheter may be placed in the patient's bladder to drain urine.
- The patient's vital signs, including the blood oxygen level, electrical activity of the heart, blood pressure, pulse, temperature, breathing, mental status, and level of consciousness, are continuously monitored during and after the surgery.

### Information for families

While the patient is in surgery, the family members wait in a designated waiting area. Some hospitals or surgery centers offer a pager to the patient's family so they can be contacted for updates about the progress of the surgery. It may be helpful for the patient to select a spokesperson from the family to communicate with the health-care providers. This may improve communication with the health-care providers as well as to other family members. The patient should also communicate his or her wishes regarding the spokesperson's telephone communications to other family members.

Educational classes may be available for family members to learn more about the patient's surgery and what to expect during the recovery.

When the surgery is complete, the surgeon usually contacts the family members to provide information about the surgery. If a problem or complication occurs during surgery, the family members are notified immediately.

### Normal results

Patients who receive proper preparation for surgery, including physical and psychological preparation, experience less anxiety and are more likely to make a quicker recovery at home, with fewer complications. Patients who perceive their surgical and

## QUESTIONS TO ASK THE DOCTOR

- Will I have to have blood transfusions during the surgery?
- Do I take my medications the day of the surgery?
- Can I eat or drink the day of the surgery? If not, how long before the surgery should I stop eating and drinking?
- How long does my type of surgery typically last?
- How long will I have to stay in the hospital after surgery?
- What kind of pain or discomfort will I experience after the surgery and what can I take to I relieve it? What type of bruising, swelling, scarring, or pain should be expected after surgery?
- What types of resources are available to me during my hospital stay, and during my recovery at home?
- After I go home from the hospital, how long will it take me to recover?
- What are the signs of infection, and what types of symptoms should I report to my doctor?
- How should I care for my incision?
- What types of medications will I have to take after surgery? How long will I have to take them?
- When will I be able I resume my normal activities? When will I be able to drive? When will I be able to return to work?
- What lifestyle changes (including diet, weight management, exercise, and activity changes) are recommended after the surgery to improve my condition?
- How often do I need to see my doctor or surgeon for follow-up visits after surgery?
- Can I receive follow-up care from my primary physician, or do I need to have follow-up visits with the surgeon?

postoperative experiences as positive report that they had minimal pain and nausea, were relaxed, had confidence in the skills of their health-care team, felt they had some control over their care, and returned to their normal activities within the expected timeframe.

## Presurgical testing

### Definition

Presurgical or preoperative testing refers to the preparation and management of a patient before surgery.

### Purpose

Presurgical testing, sometimes called preoperative testing, prepares a patient for surgery psychologically and physically.

### Demographics

The U.S. Department of Health and Human Services' National Center for Health Statistics reported

more than 44.9 million inpatient surgical procedures (requiring an overnight hospital stay) performed in the United States in 2005. About 50 million outpatient surgical procedures (in which the patient goes home the same day of surgery) were performed in that year.

Obstetrical, cardiovascular, digestive, musculoskeletal, and neurological surgeries are among the majority of the inpatient surgical procedures performed. The majority of outpatient surgeries were performed on the digestive system, eyes, musculoskeletal system, female reproductive organs, and urinary system.

In recent years there has been a change in attitude toward routine presurgical testing. In the years following World War II, administering routine laboratory tests to patients before surgery became part of normal clinical procedure. It was thought that such testing would help doctors to detect abnormalities before surgery that might lead to complications during or after the operation. Until the 1980s few surgeons evaluated either the clinical or the cost-effectiveness of these tests. In the mid-1980s, however, some researchers began to publish papers showing that preoperative testing was not only expensive but also did not necessarily benefit patients. One study published in the *Journal of the American Medical Association* in 1985 noted that 60% of a sample group of 2000 patients had had laboratory tests ordered for no apparent reason. Of the abnormal test findings, only 0.22% influenced preoperative management of the patients.

Newer recommendations for presurgical testing of healthy patients undergoing **elective surgery** are as follows:

- Consider a complete patient history and thorough physical examination the most important part of preoperative testing.
- The patient's hemoglobin level should be tested before for major surgery with significant expected blood loss or CBC count if the cost is not substantially increased.
- Serum creatinine level (a blood test) should be tested in people older than 40 years.
- Electrocardiogram (ECG or EKG) for patients over 40.
- Chest x-ray for patients older than 60.
- It is not necessary to repeat any laboratory test if the results were normal within 4 months of the scheduled surgery and if there has been no change in the patient's health.

Patients with heart disease or lung disease, or undergoing **emergency surgery**, require more complete evaluation.

## KEY TERMS

**Biopsy**—The removal of a small sample of tissue for analysis to determine a diagnosis.

**Bone densitometry test**—A test that quickly and accurately measures the density of bone.

**Catheter**—A small, flexible tube used to deliver fluids or medications.

**Chest x ray**—A diagnostic procedure in which a small amount of radiation is used to produce an image of the structures of the chest (heart, lungs, and bones) on film.

**Echocardiogram**—An imaging procedure used to create a picture of the heart's movement, valves and chambers. The test uses high-frequency sound waves that come from a hand wand placed on the chest. Echocardiogram may be used in combination with Doppler ultrasound to evaluate the blood flow across the heart's valves.

**Electrocardiogram (ECG, EKG)**—A test that records the electrical activity of the heart using small electrode patches attached to the skin on the chest.

**Pulmonary function test**—A test that measures the capacity and function of the lungs, as well as the blood's ability to carry oxygen. During the test, patient breathes into a device called a spirometer.

## Description

A planned surgery usually involves a surgical consultation, presurgical testing, the surgery itself, and **recovery at home**.

During the surgical consultation, the patient meets with the surgeon or a member of the surgeon's health-care team to discuss the surgery and other potential treatment options for the patient's medical condition. A thorough review of the patient's medical history and a complete physical exam are performed at this time. The medical review includes an evaluation of the patient's previous and current medical conditions, surgeries and procedures, medications, and any other health conditions, such as allergies, that may impact the surgery.

The **surgical team** will ensure that the patient understands the potential benefits and risks of the procedure. Patient education may include one-on-one instruction from a health care provider, educational sessions in a group setting, or self-guided learning videos or modules. Informative and instructional

handouts are usually provided to explain specific presurgical requirements.

After attending the surgical consultation, the patient may desire a **second opinion** to confirm the first doctor's treatment recommendations.

## Diagnosis/Preparation

Presurgical testing includes a variety of tests, patient education, and meetings with the health care team to inform the patient about what to expect before the procedure and during the recovery. Presurgical testing is generally scheduled within one week before the surgery.

Several tests are performed before surgery to provide complete information about the patient's overall health, to prepare the patient for anesthesia (as applicable), and to identify and treat any potential problems ahead of time. Each surgery patient does not have the same presurgery tests. In addition to checking the patient's **vital signs** (temperature, blood pressure, and pulse), more common tests include:

- blood tests
- urine tests
- chest x rays
- pulmonary function tests
- computed tomography scan (CT or CAT scan)
- heart function tests that may include an electrocardiogram or echocardiogram

If the patient recently had these tests performed (within the past six months), he or she can request the test results be forwarded to the surgical center.

Before some surgical procedures, such as valve surgery, a complete dental exam is needed to reduce the risk of infection. Other precautions will be taken before the surgery to reduce the patient's risk of infection.

**Informed consent** is an educational process between health-care providers and patients. Before any procedure is performed, the patient is asked to sign a consent form. Before signing the form, the patient should understand the nature and purpose of the diagnostic procedure or treatment, the risks and benefits of the procedure, and alternatives, including the option of not proceeding with the test or treatment. During the discussion about the procedure, the health-care providers are available to answer the patient's questions about the consent form or procedure.

Advance directives are legal documents that increase a patient's control over medical decisions. A patient may decide medical treatment in advance, in the event that he or she becomes physically or mentally unable to communicate his or her wishes. Advance directives either state

what kind of treatment the patient wants to receive (**living will**), or authorize another person to make medical decisions for the patient when he or she is unable to do so (**durable power of attorney**).

Advance directives are not required and may be changed or canceled at any time. Any change should be written, signed, and dated in accordance with state law, and copies should be given to the physician and to others who received original copies. Advance directives can be revoked either in writing or by destroying the document.

Advance directives are not a do-not-resuscitate (DNR) order, which indicates that a person—usually with a terminal illness or other serious medical condition—has decided not to have **cardiopulmonary resuscitation** (CPR) performed in the event that his or her heart or breathing stops.

Patients who will undergo any surgical procedure are encouraged to quit smoking and stop using tobacco products at least two weeks before the procedure, and to make a commitment to be a nonsmoker after the procedure. Quitting smoking before surgery helps the patient recover more quickly from surgery. There are several **smoking cessation** programs available in the community. The patient should ask a health-care provider for more information if he or she needs help quitting smoking.

The presurgical evaluation may include meetings with the anesthesiologist, surgeon, nurse clinicians, and other health-care providers who will manage the patient's care during and after surgery, such as a dietitian, social worker, or rehabilitation specialist.

The patient's surgery time may not be determined until the business day before the scheduled surgery. The patient may be instructed to call the surgical center to find out the time of the scheduled surgery.

Patients are told to come to the surgery center far enough in advance (usually about two hours prior to the scheduled surgery time) so they can be properly prepared for surgery. In some cases, the patient's surgery may need to be rescheduled if another patient requires emergency surgery at the patient's scheduled time.

Some surgery centers offer services such as guided imagery and relaxation tapes, massage therapy, or other complementary techniques to reduce a patient's level of stress and anxiety before a surgical procedure.

Guided imagery is a form of focused relaxation that coaches the patient to visualize calm, peaceful images. Several research studies have proven that guided imagery can significantly reduce stress and anxiety before and after surgical and medical procedures and help the patient recover more rapidly. Guided

imagery tapes are available at many major bookstores and from some surgery centers. The patient listens to the guided imagery tapes on his or her own CD or tape player before and after the surgery. The patient may even be able to continue listening to the tapes during the procedure, depending on the type of procedure being performed.

Blood transfusions may be necessary during surgery. A blood **transfusion** is the delivery of whole blood or blood components to replace blood lost through trauma, surgery, or disease. About one in three hospitalized patients will require a blood transfusion. The surgeon can provide an estimate of how much blood the patient's procedure may require.

To decrease the risk of infection and immunologic complications, some surgery centers offer a preoperative **blood donation** program. Autologous blood (blood taken from the patient) is the safest blood available for transfusion, since there is no risk of disease transmission. Methods of autologous donation or collection include:

- Intraoperative blood collection: The blood lost during surgery is processed and the red blood cells are reinfused during or immediately after surgery.
- Preoperative donation: The patient donates blood once a week for about one to three weeks before surgery. The blood is separated, and the blood components needed are reinfused during surgery.
- Immediate preoperative hemodilution: The patient donates blood immediately before surgery to decrease the loss of red blood cells during surgery. After donating, the patient receives fluids to compensate for the amount of blood removed. Since the blood is diluted, fewer red blood cells are lost from bleeding during surgery.
- Postoperative blood collection: Blood lost from the surgical site right after surgery is collected and reinfused after the surgical site has been closed.

The surgeon determines what type of blood collection process, if any, is appropriate.

Depending on the type of surgery scheduled, certain medications may be prescribed or restricted before the surgery. The health-care team will provide specific guidelines. If certain medications need to be restricted before surgery, the patient will receive a complete list of the medications (including prescription, over-the-counter, and herbal medications) to avoid taking before the scheduled surgery.

Prescribed medications that need to be taken within 12 hours before surgery should be swallowed with small sips of water.

Before most surgeries, the patient is advised not to eat or drink anything after midnight the evening before the surgery. This fast includes no smoking and no gum chewing. The patient should not drink any alcoholic beverages for at least 24 hours before surgery, unless instructed otherwise.

Most patients are admitted to the surgery center or hospital the same day as the scheduled surgery. The patient should bring a list of current medications, allergies, and appropriate medical records upon admission to the surgery center.

The patient should arrange for transportation home, since the effects of anesthesia and other medications given before surgery make it unsafe to drive.

## Private insurance plans

### Definition

Private insurance plans include all forms of health insurance that are not funded by the government.

### Purpose

These plans are intended to protect their beneficiaries from the high costs that may be incurred for health care. Most private insurance plans in the United States are employment-based.

Of the nearly 243 million Americans who are covered by private health insurance, approximately nine in 10 (215 million, or 88%) are enrolled in employment-based plans.

### Description

Private health insurance plans may be purchased on an individual or group basis. Most group plans are offered by large employers, although some are available through voluntary associations. Individual policies are usually more expensive than group policies. Furthermore, they may have additional coverage restrictions.

## KEY TERMS

**Co-insurance**—The percentage of health care charges that an insurance company pays after the beneficiary pays the deductible. Most co-insurance percentages are 70–90%.

**Deductible**—An amount of money that an insured person is required to pay on each claim made on an insurance policy.

**Indemnity**—Protection, as by insurance, against damage or loss.

**Indemnity plans**—Private health insurance plans that allow the policyholder to choose any physician or hospital when health care is needed.

**Long-term care (LTC) insurance**—A type of private health insurance intended to cover the cost of long-term nursing home or home health care.

**Medigap**—A group of 10 standardized private health insurance policies intended to cover the coinsurance and deductible costs not covered by Medicare.

**Portability**—A feature that allows employees to transfer health insurance coverage or other benefits from one employer to another when they change jobs.

**Preferred provider organizations (PPOs)**—Private health insurance plans that require beneficiaries to select their health care providers from a list approved by the insurance company.

**Premium**—The amount paid by an insurance policyholder for insurance coverage. Most health insurance policy premiums are payable on a monthly basis.

There are several major categories of private health insurance in the United States.

### *Indemnity plans*

Indemnity plans are private insurance plans that allow beneficiaries to choose any physician or hospital when they need medical care. Most indemnity plans have a deductible, or amount that the policyholder must pay before the plan will cover any costs. After the deductible has been satisfied, indemnity plans pay a co-insurance percentage, most often 70–90% of the charges. The beneficiary pays the remainder of the bill.

### *Preferred provider organization (PPO) plans*

PPO plans are similar to indemnity plans in that they usually have both a deductible and a co-insurance percentage. Unlike indemnity plans, PPOs offer a list of

physicians and hospitals from which enrollees must select in order to receive the plan's maximum benefit. PPOs tend to be less expensive than indemnity plans because health care providers are often willing to reduce their fees in order to participate in these plans. Many large companies have moved their insured employees into PPOs because of their cost effectiveness.

A person enrolled in a PPO can choose to seek care from a non-network provider. This is called going out of network. Some people find this beneficial because it allows continuity of care from an existing provider. Enrollees may also propose their physician for membership in the PPO so that continuity of service may be provided.

### *Health maintenance organization (HMO) plans*

HMOs usually have no deductible. Beneficiaries are charged a small co-payment, typically between \$5 and \$25 per visit, and the plan covers all other charges. The list of preferred providers is generally smaller than that of a PPO. In most HMOs, each beneficiary selects a primary care physician who is responsible for all health care needs. Referrals to specialists must be made through the primary care physician. Like PPOs, HMOs are usually able to charge lower premiums because their participating health care providers agree to accept substantially reduced fees.

### *Long-term care (LTC) insurance*

**Long-term care insurance**, or LTC, is a type of private health insurance intended to cover the cost of custodial or nursing **home care**. It can be very expensive, and persons considering this form of insurance should not purchase it if the premiums cause financial hardship in the present.

### *Medigap insurance plans*

**Medicare** does not offer complete health insurance protection. Medigap insurance is a type of plan intended to supplement Medicare coverage. There are 10 standard Medigap benefit packages. These are identified by the letters A through J, and are available in most states, United States territories, and the District of Columbia. Medigap policies pay most or all of the co-insurance amounts charged by Medicare. Some Medigap policies cover Medicare deductibles.

### *Medical savings accounts (MSAs)*

Medical savings accounts are not health insurance plans in the strict sense, but offer a partial alternative to expensive individual private insurance plans. MSAs are similar to Individual Retirement Accounts (IRAs),

and have been considered a significant tax break for self-employed individuals. They were created as a four-year pilot project by the Health Insurance Portability and Accountability Act (HIPAA) of 1996. Effective December 31, 2000, the federal government issued an extension on these accounts for two years. The extension is currently renewed every year.

An MSA must be combined with a qualified high-deductible private health plan. Without an MSA, a self-employed individual can deduct qualified medical expenses only under the itemized deductions of a 1040 tax form, and the expenses must exceed 7.5% of the adjusted gross income.

### *The cost of health insurance*

The cost of private health insurance has risen steadily over the past two decades, largely because of the rising cost of health care in the United States. Between 1980 and 1995, the total amount spent on health care in the United States each year rose from \$247.2 billion to \$1.04 trillion, more than a 400% increase. Between 1995 and 2006, the amount doubled again, to more than \$2 trillion per year. The reasons for the escalating costs include the following:

- Increased longevity. The life expectancy of most Americans is approximately 76 years. When older people join an insured group, the entire group's health care risks and costs rise.
- Advances in medical technology. New technology is often expensive.

The rising costs of health insurance over the past 30 years have caused many employers to curtail or drop health insurance as an employee benefit. The cost of health insurance premiums increased from \$16.8 billion in 1970 to \$310 billion in 1995. By 2006, employers were spending \$11,400 per year to insure a family of four. Many employers have increased the amount of money employees are expected to contribute toward their health care. Others, particularly smaller businesses, do not offer health insurance at all. A 1997 study found that only 34% of workers in smaller businesses were covered through their employers, whereas 82% of employees in the largest companies were covered. Experts feel that this trend will continue. Workers in large-employer health insurance plans generally have policies that cover more health services, have lower deductibles, and offer more opportunities to enroll in HMOs.

### *Uninsured persons*

The U.S. Census Bureau reported in 1997 that 43.4 million people in the United States, or 16.1% of

the population, had no health insurance coverage. Between 1998 and 1999, both the number and proportion of uninsured Americans declined slightly, to 42.6 million and 15.5% respectively. As of 2005, the federal government estimated that nearly 47 million Americans, or 16 percent of the population, were without health insurance.

Some workers do not have health insurance because they cannot afford it. In the 1950s, employer-based health insurance served most American families reasonably well because many workers were employed by large firms and remained with them for life. The trend over the past two decades is employment by small firms that do not offer health insurance as a benefit, and a tendency to change employers every few years. Most uninsured workers are self-employed, work only part-time, or hold low-wage jobs that do not give them access to lower-cost employer-sponsored group plans. Workers in these three categories do not qualify for coverage by government programs for low-income people.

The other major category of uninsured people includes those who cannot purchase private insurance at affordable rates because they are likely to need expensive medical services. Those who have a high risk of developing cancer or are HIV-positive may not be able to obtain coverage from any insurance company. As early as the 1980s, some insurance companies began introducing clauses that excluded or restricted benefits for persons with pre-existing conditions. These clauses denied private insurance to anyone already diagnosed with a serious medical condition. One of the goals of the Health Insurance Portability and Accountability Act (HIPAA) of 1996 was to help workers who could not change jobs because they had family members with serious health problems. In the past, they would have been denied health insurance by the preexisting condition clauses in the new employer's plan. HIPAA requires employer-sponsored insurance plans to accept transfers from other plans without imposing preexisting condition clauses.

An individual private health insurance plan can be expensive and restrictive. It may, however, be the only choice for a consumer who is not employed; self-employed; or is a new hire at a company and must wait several months or more before the company's coverage takes effect.

### *Tax credit proposals*

One approach to the rising costs of private health insurance that is gaining bipartisan political support is to offer tax credits that would allow more Americans

to purchase health insurance. The present federal tax code favors workers who already have employer-sponsored health insurance. Supporters of the tax credit approach maintain that it would give workers a wider choice of health plans, create greater portability of health insurance, and encourage groups other than employment-based populations (e.g., church groups, unions, fraternal organizations) to sponsor insurance plans for their members.

*See also* Long-term insurance.

## Prophylaxis, antibiotic

### Definition

A prophylaxis is a measure taken to maintain health and prevent the spread of disease. Antibiotic prophylaxis is the focus of this article and refers to the use of **antibiotics** to prevent infections.

### Purpose

Antibiotics are well known for their ability to treat infections. But some antibiotics also are prescribed to prevent infections. This usually is done only in certain situations or for people with particular medical problems.

For example, people with abnormal heart valves have a high risk of developing heart valve infections even after only minor surgery. This happens because bacteria from other parts of the body get into the bloodstream during surgery and travel to the heart valves. To prevent these infections, people with heart valve problems often take antibiotics before having any kind of surgery, including dental surgery.

Antibiotics also may be prescribed to prevent infections in people with weakened immune systems such as those with AIDS or people who are having chemotherapy treatments for cancer. But even healthy people with strong immune systems may occasionally be given preventive antibiotics—if they are having certain kinds of surgery that carry a high risk of infection, or if they are traveling to parts of the world where they are likely to get an infection that causes diarrhea, for example.

In all of these situations, a physician should be the one to decide whether antibiotics are necessary. Unless a physician says to do so, it is not a good idea to take antibiotics to prevent ordinary infections.

Because the overuse of antibiotics can lead to resistance, drugs taken to prevent infection should be used only for a short time.

### Description

Among the drugs used for antibiotic prophylaxis are amoxicillin (a type of penicillin) and **fluoroquinolones** such as ciprofloxacin (Cipro) and trovafloxacin (Trovan). These drugs are available only with a physician's prescription and come in tablet, capsule, liquid, and injectable forms.

For surgical prophylaxis, the cephalosporin antibiotics are usually preferred. This class includes cefazolin (Ancef, Kefzol), cefamandole (Mandol), cefotaxime (Claforan), and others. The choice of drug depends on its spectrum and the type of bacteria that are most likely to be encountered. For example, surgery on the intestines, which have many anaerobic bacteria, might call for cefoxitin (Mefoxin), while in heart surgery, where there are no anaerobes, cefazolin might be preferred.

### Recommended dosage

The recommended dosage depends on the type of antibiotic prescribed and the reason it is being used. For the correct dosage, the patient is advised to check with the physician or dentist who prescribed the medicine or the pharmacist who filled the prescription. The patient is recommended to be sure to take the medicine

## KEY TERMS

**AIDS**—Acquired immunodeficiency syndrome. A disease caused by infection with the human immunodeficiency virus (HIV). In people with this disease, the immune system breaks down, opening the door to other infections and some types of cancer.

**Antibiotic**—A medicine used to treat infections.

**Chemotherapy**—Treatment of an illness with chemical agents. The term is typically used to describe the treatment of cancer with drugs.

**Immune system**—The body's natural defenses against disease and infection.

exactly as prescribed, and not to take more or less than directed, and to take the medicine only for as long as the physician or dentist says to take it.

The recommended dose of prophylactic antibiotic for surgery has varied with studies. At one time, it was common to give a dose of antibiotic when the patient was called to the **operating room**, and to continue the drug for 48 hours after surgery. More recent studies indicate that a single antibiotic dose, given immediately before the start of surgery, may be just as effective in preventing infection, while reducing the risk of drug side effects.

### Precautions

The warnings listed below refer primarily to the effects of the drugs when taken in multiple doses. When prophylactic antibiotics are used as a single dose, adverse effects are very unlikely. The only exceptions are for people who are allergic to the antibiotic used. Since **cephalosporins** are closely related to penicillins, people who are allergic to penicillins should avoid cephalosporin antibiotics.

If the medicine causes nausea, vomiting, or diarrhea, the patient is advised to check with the physician or dentist who prescribed it as soon as possible. Patients who are taking antibiotics before surgery should not wait until the day of the surgery to report problems with the medicine. The physician or dentist needs to know right away if problems occur.

For other specific precautions, the patient is advised to see the entry on the type of drug prescribed such as penicillins or fluoroquinolones.

### Side effects

Antibiotics may cause a number of side effects. For details, the patient is advised to see entries on

specific types of antibiotics. Anyone who has unusual or disturbing symptoms after taking antibiotics should get in contact with the prescribing physician.

### Interactions

Whether used to treat or to prevent infection, antibiotics may interact with other medicines. When this happens, the effects of one or both of the drugs may change or the risk of side effects may be greater. Anyone who takes antibiotics for any reason should inform the physician about all the other medicines he or she is taking and should ask whether any possible interactions may interfere with drugs' effects. For details of drug interactions, the candidate is advised to see entries on specific types of antibiotics.

## Prothrombin time

### Definition

The prothrombin time test belongs to a group of blood tests that assess the clotting ability of blood. The test is also known as the pro time or PT test.

### Purpose

The PT test is used to monitor patients taking certain medications as well as to help diagnose clotting disorders.

### Diagnosis

Patients who have problems with delayed blood clotting are given a number of tests to determine the cause of the problem. The prothrombin test specifically evaluates the presence of factors VIIa, V, and X, prothrombin, and fibrinogen. Prothrombin is a protein in the liquid part of blood (plasma) that is converted to thrombin as part of the clotting process. Fibrinogen is a type of blood protein called a globulin; it is converted to fibrin during the clotting process. A drop in the concentration of any of these factors will cause the blood to take longer to clot. The PT test is used in combination with the **partial thromboplastin time (PTT)** test to screen for hemophilia and other hereditary clotting disorders.

### Monitoring

The PT test is also used to monitor the condition of patients who are taking warfarin (Coumadin). Warfarin is a drug that is given to prevent clots in the deep veins of the legs and to treat pulmonary embolism. It interferes with blood clotting by lowering the liver's production of certain clotting factors.

### Description

A sample of the patient's blood is obtained by venipuncture. The blood is collected in a tube that contains sodium citrate to prevent the clotting process from starting before the test. The blood cells are separated from the liquid part of blood (plasma). The PT test is performed by adding the patient's plasma to a protein in the blood (thromboplastin) that converts prothrombin to thrombin. The mixture is then kept in a warm water bath at 37°C for one to two minutes. Calcium chloride is added to the mixture in order to counteract the sodium citrate and allow clotting to proceed. The test is timed from the addition of the calcium chloride until the plasma clots. This time is called the prothrombin time.

### Preparation

The doctor should check to see if the patient is taking any medications that may affect test results. This precaution is particularly important if the patient is taking warfarin, because there are a number of

## KEY TERMS

**Disseminated intravascular coagulation (DIC)**—A condition in which spontaneous bleeding and clot formation occur throughout the circulatory system. DIC can be caused by transfusion reactions and a number of serious illnesses.

**Fibrin**—The protein formed as the end product of the blood clotting process when fibrinogen interacts with thrombin.

**Fibrinogen**—A type of blood protein called a globulin that interacts with thrombin to form fibrin.

**Plasma**—The liquid part of blood, as distinct from blood cells.

**Prothrombin**—A protein in blood plasma that is converted to thrombin during the clotting process.

**Thrombin**—An enzyme in blood plasma that helps to convert fibrinogen to fibrin during the last stage of the clotting process.

**Thromboplastin**—A protein in blood that converts prothrombin to thrombin.

**Warfarin**—A drug given to control the formation of blood clots. The PT test can be used to monitor patients being treated with warfarin.

medications that can interact with warfarin to increase or decrease the PT time.

## Aftercare

Aftercare consists of routine care of the area around the puncture site. Pressure is applied for a few seconds and the wound is covered with a bandage.

## Risks

The primary risk is mild dizziness and the possibility of a bruise or swelling in the area where the blood was drawn. The patient can apply moist warm compresses.

## Normal results

The normal prothrombin time is 11–15 seconds, although there is some variation depending on the source of the thromboplastin used in the test. (For this reason, laboratories report a normal control value along with patient results.) A prothrombin time within this range indicates that the patient has normal amounts of clotting factors VII and X.

## Abnormal results

A prolonged PT time is considered abnormal. The prothrombin time will be prolonged if the concentration of any of the tested factors is 10% or more below normal plasma values. A prolonged prothrombin time indicates a deficiency in any of factors VII, X, V, prothrombin, or fibrinogen. It may mean that the patient has a vitamin K deficiency, a liver disease, or disseminated intravascular coagulation (DIC). The prothrombin time of patients receiving warfarin therapy will also be prolonged—usually in the range of one and one half to two times the normal PT time. A PT time that exceeds approximately two and a half times the control value (usually 30 seconds or longer) is grounds for concern, as abnormal bleeding may occur.

## Morbidity and mortality rates

Morbidity rates are excessively miniscule. The most common problems are minor bleeding and bruising. Since neither are reportable events, morbidity can only be estimated. Mortality is essentially zero.

## Alternatives Resources

There are no alternatives to a prothrombin time.

## Precautions

The only precaution needed is to clean the venipuncture site with alcohol.

## Side effects

The most common side effects of a prothrombin time test are minor bleeding and bruising.

# Proton pump inhibitors

## Definition

The proton pump inhibitors are a group of drugs that reduce the secretion of gastric (stomach) acid. They act by binding with the enzyme  $H^+$ ,  $K(+) - ATPase$ , *hydrogen/potassium adenosine triphosphatase*, which is sometimes referred to as the proton pump. This enzyme causes parietal cells of the stomach lining to produce acid.

Although they perform much the same functions as the histamine H-2 receptor blockers, the proton pump inhibitors reduce stomach acid more and over a longer period.

## Purpose

Proton pump inhibitors are used to treat ulcers; gastroesophageal reflux disease (GERD), a condition in which backward flow of acid from the stomach causes heartburn and injury of the food pipe (esophagus); and conditions in which the stomach produces too much acid, such as Zollinger-Ellison syndrome. Omeprazole is used in combination with other medications to treat recurrent ulcers caused by *helicobacter pylori* infections.

Two of the proton pump inhibitors, lansoprazole and omeprazole, have been used to improve pancreatic enzyme absorption in cystic fibrosis patients with intestinal malabsorption.

Proton pump inhibitors may be used to protect against the ulcerogenic effects of non-steroidal anti-inflammatory drugs and to help heal ulcers caused by these drugs.

## Description

There are five drugs in this class: esomeprazole (Nexium), lansoprazole (Prevacid), omeprazole (Prilosec), pantoprazole (Protonix), and rabeprazole (AcipHex). They act in a similar manner, and their cautions and adverse effects are similar.

The products are generally formulated as enteric-coated granules. Absorption does not start until the granules have left the stomach and reached the intestine, so the onset of action is delayed about an hour, subject to gastric emptying time. Since they act slowly, proton pump inhibitors are not a suitable alternative to antacids which have a rapid effect.

Although these drugs are eliminated from the body relatively quickly, usually within 90 minutes of absorption, they all work for over 24 hours after a dose. This is because the factor that determines duration of action is how long it takes the body to replace the  $H^+$ ,  $K(+) - ATPase$ . There is some build up over time. For example, a single dose of lansoprazole reduces stomach acid by 71%, but after a week of regular dosing, the acid reduction rises to 80%.

For treatment of recurrent ulcers, the proton pump inhibitors are part of combination therapy that uses an antibiotic (occasionally two **antibiotics**) and proton pump inhibitor. There are a number of regimens, and while they may vary in the selection of specific drugs, or even types of drugs used, usually they include a proton pump inhibitor. The cure rates are all within similar ranges for these regimens.

## Recommended dosage

Dose varies with the indication. The following are commonly prescribed doses:

- Esomeprazole: 20 to 40 mg once a day.
- Lansoprazole: 15 to 30 mg once a day.
- Omeprazole: 20 to 40 mg once a day.
- Pantoprazole: 40 mg once or twice a day.
- Rabeprazole: 20 mg once a day. In hypersecretory conditions, doses as high as 60 mg twice daily have been reported.

In the above examples, the lower dose is usually adequate for GERD, while the higher dose may be required for ulcer therapy or hypersecretory conditions.

## Precautions

Proton pump inhibitors should not be given to any patient who has shown a reaction to any of the components of the drug or a related drug. Proton pump inhibitors should also not be given to patients with severe liver disease.

Omeprazole is pregnancy category C, while esomeprazole, lansoprazole, rabeprazole, and pantoprazole are category B. As of 2008, there are no adequate and well-controlled studies concerning the effects of these drugs on pregnant women. These drugs should be used during pregnancy only if the potential benefit justifies the risk to the fetus. Because the proton pump inhibitors are excreted into breast milk, they should not be used by women who are breastfeeding their babies.

The proton pump inhibitors may mask the symptoms of stomach cancer.

## Side effects

The proton pump inhibitors are relatively safe drugs. The most commonly observed adverse effects are constipation, diarrhea, dizziness, headache, skin itch, and skin rash. Less often, the following adverse effects have been reported: abdominal pain with cramps, appetite changes, and nausea.

The following adverse effects are extremely rare but have been reported with this class of drugs:

- acute pancreatitis
- anxiety
- cough
- depression
- drug toxin-related hepatitis
- erythema multiforme

## KEY TERMS

**Antacid**—A substance that counteracts or neutralizes acidity, usually of the stomach. Antacids have a rapid onset of action compared to histamine H-2 receptor blockers and proton pump inhibitors, but they have a short duration of action and require frequent dosing.

**Cystic fibrosis**—A hereditary disease that appears in early childhood, involves functional disorder of digestive glands, and is marked especially by faulty digestion due to a deficiency of pancreatic enzymes, by difficulty in breathing due to mucus accumulation in airways, and by excessive loss of salt in the sweat.

**Enteric coat**—A coating put on some tablets or capsules to prevent their disintegration in the stomach. The contents of coated tablets or capsules will be released only when the dose reaches the intestine. This may be done to protect the drug from stomach acid, to protect the stomach from drug irritation, or to delay the onset of action of the drug.

**GERD**—A chronic condition in which the lower esophageal sphincter allows gastric acids to reflux into the esophagus, causing heartburn, acid indigestion, and possible injury to the esophageal lining.

**Malabsorption**—Defective or inadequate absorption of nutrients from the intestinal tract.

**Parietal cells**—Cells of the gastric glands that secrete hydrochloric acid.

**Recurrent ulcer**—Stomach ulcers that return after apparently complete healing. These ulcers appear to be caused by helicobacter pylori infections and can generally be successfully treated with a combination of antibiotics and gastric acid reducing compounds, particularly the proton pump inhibitors.

- flu-like symptoms
- myalgia
- Stevens-Johnson syndrome
- thrombocytopenia
- toxic epidermal necrolysis
- ulcerative colitis
- upper respiratory hypersensitivity reaction
- upper respiratory infection
- vomiting

## Interactions

Proton pump inhibitors should not be used in conjunctions with the anti-retroviral (anti-AIDS) drug atazanavir (Rayataz). The conjunction may reduce the effectiveness of the atazanavir. Proton pump inhibitors should not be used in combination with the anti-fungal drugs itraconazole or ketoconazole. This combination may reduce the effectiveness of the anti-fungal drugs.

## Pulse oximeter

### Definition

The pulse oximeter is a photoelectric instrument for measuring oxygen saturation of blood.

### Purpose

A pulse oximeter measures the amount of oxygen present in blood by registering pulsations within an arteriolar bed (an area between arteries and capillaries). It is a noninvasive method widely used in hospitals on newborns, persons with pulmonary disorders, and individuals undergoing pulmonary and cardiac procedures. Oxygen levels can be estimated during **exercise**, surgery, or other medical procedures, or while a person is asleep.

### Description

The oximeter consists of a light-emitting diode (LED), a photodetector probe containing a permanent or disposable sensor, alarms for pulse rate and oxygen levels, a display screen, and cables. The device works by emitting beams of red and infrared light that are passed through a pulsating arteriolar bed. Sensors detect the amount of light absorbed by oxyhemoglobin and deoxyhemoglobin in the red blood cells. The ratio of red to infrared light measured by the photodetector indicates the amount of oxygen present in the

**A pulse oximeter uses infrared light and a photo sensor to detect the amount of oxygen in a patient's blood.** (Illustration by Argosy. Cengage Learning, Gale.)

## KEY TERMS

**Arteriolar bed**—An area in which arterioles cluster between arteries and capillaries.

**Arterioles**—The smallest branches of arteries.

**Capillaries**—Tiny blood vessels with a diameter of a red blood cell through which a single layer of cells flows.

**Deoxyhemoglobin**—Hemoglobin with oxygen removed.

**Hemoglobin**—The iron-containing protein in the blood that transports oxygen from the lungs to all parts of the body.

**Oxyhemoglobin**—Hemoglobin combined with oxygen.

blood. The sensor is attached to the body over the arteriolar area in the ear, the fingertip, the big toe, or across the bridge of the nose. Clip sensors can be used on fingers or the earlobe.

The pulse oximeter is widely used in most hospitals and in research laboratories that study pulmonary function. Oximeters are used in hospital settings such as intensive care units, pulmonary units, and in health care centers. Portable hand-held devices are available,

and are used to spot check patients and for in-home use under the supervision of a physician.

## Usage

Several steps can be taken to improve the accuracy of readings. If possible, the patient should not smoke 24 hours prior to pulse oximetry. Fingernail polish should be removed if the oximeter will be attached to the finger. For people with poor circulation, hands should be slowly warmed with warm towels before attaching the oximeter. Abnormally high or low temperatures, as well as reduced hemoglobin, can influence the amount of oxygen adhering to the hemoglobin within the red blood cells, altering the reading. The sensor should be wrapped securely around the finger to prevent outside light from interfering with the reading, which could render it invalid. The device must not be used near flammable anesthetics.

## Pyloroplasty

### Definition

Pyloroplasty is a surgical procedure in which the pylorus valve at the lower portion of the stomach is cut and resutured, relaxing and widening its muscular opening (pyloric sphincter) into the duodenum (first part of the small intestine). Pyloroplasty is a treatment for patients at high risk for gastric or peptic ulcer disease (PUD).

### Purpose

Pyloroplasty surgery enlarges the opening through which stomach contents are emptied into the intestine, allowing the stomach to empty more quickly. A pyloroplasty is performed to treat the complications of PUD or when medical treatment has not been able to control PUD in high-risk patients.

### Demographics

Nearly four million people in the United States have PUD; about five adults in 100,000 will develop an ulcer. About 1.7% of children being treated in general pediatric practices are diagnosed with PUD. The presence of ulcer-causing *Helicobacter pylori* bacteria occurs in 10% of the population in industrialized countries and is believed to cause 80–90% of primary ulcers. In the United States, *H. pylori* infection occurs

more frequently in black and Hispanic populations than in white. The frequency of secondary ulcers (caused by other existing conditions) is not known as it depends on the frequency of other illnesses, chronic diseases, and drug use. Primary and secondary PUD can occur in patients of all ages. Primary PUD is rare in children under age 10, increasing during adolescence. Secondary PUD is more prevalent in children under age six.

### Description

Peptic ulcer disease develops when there is an imbalance between normal conditions that protect the lining (mucosa) of the stomach and the intestines and conditions that disrupt normal functioning of the lining. Protective factors include the water-soluble mucosal gel layer, the production of bicarbonate in the lining to balance acidity, the regulation of gastric acid (stomach acid) secretion, and blood flow in the lining. The aggressive factors that work against this protective gastric-wall system are excessive acid production, *H. pylori* bacterial infection, and a reduced blood flow (ischemia) in the mucosal lining. These aggressive factors can cause inflammation and ulcer development. A peptic ulcer is a type of sore or hole (perforation) that forms on the lining of the stomach (gastric ulcer) or intestine (duodenal ulcer), when the lining has been eaten away by stomach acid and digestive juices. Peptic ulcers can be primary, caused by *H. pylori* infection, or secondary, caused by excess acid production, stress, use of medications, and other underlying conditions that disrupt the gastric environment. Although *H. pylori* is believed to cause the majority of all ulcers, not all people infected with it develop ulcers. In high-risk individuals, the bacteria more readily disturb the balance between good factors and destructive factors, upsetting the protective function of the stomach and intestine lining. An ulcer develops when the lining can no longer protect the organs. Secondary ulcers are usually found in the stomach; primary ulcers can be in the stomach or intestine.

Other factors that contribute to mucosal inflammation and ulceration include:

- alcohol and caffeine use
- non-steroidal anti-inflammatory drugs (NSAIDs)
- aspirin
- cigarette smoking
- exposure to certain irritating chemicals
- emotional disturbances and prolonged stress
- traumatic injuries and burns

In a pyloroplasty, an incision is made in the area that connects the stomach to the duodenum (small intestine), called the pylorus (A). The pylorus is divided laterally (B), and then stitched longitudinally (C and D), allowing for a larger connection. (Illustration by GGS Information Services. Cengage Learning, Gale.)

- respiratory failure
- blood poisoning
- critical illnesses that create imbalances in body chemistry

Symptoms of gastric or peptic ulcer include burning pain, nausea, vomiting, loss of appetite, bloating, burping, and losing weight.

When PUD is diagnosed or high risk established, medical treatment will begin to treat *H. pylori* infection if present and to restore balanced conditions in the mucosal lining. Any underlying condition may be treated simultaneously, including respiratory disorders, fluid imbalance, or stomach and digestive disorders. Medications may be prescribed to help correct gastric disturbances and control gastric acid secretion.

## KEY TERMS

**Gastric (or peptic) ulcer**—An ulcer (sore or hole) in the stomach lining, duodenum, or other part of the gastrointestinal system.

**Pyloric sphincter**—A broad band of muscle in the pylorus valve at the bottom end of the stomach.

**Pylorus**—The valve at the bottom end of the stomach that releases food from the stomach into the intestines.

**Vagotomy**—A surgical procedure in which the nerves that stimulate stomach acid production and gastric motility (movement) are cut.

Certain drugs that are prescribed for other conditions, especially NSAIDs, may be discontinued if they are known to cause inflammation. Adult patients may be advised to discontinue alcohol and caffeine use and to stop smoking.

When medical treatment alone is not able to improve the conditions that cause PUD, a pyloroplasty procedure may be recommended, particularly for patients with stress ulcers, perforation of the mucosal wall, and gastric outlet obstruction. The surgery involves cutting the pylorus lengthwise and resuturing it at a right angle across the cut to relax the muscle and create a larger opening from the stomach into the intestine. The enlarged opening allows the stomach to empty more quickly. A pyloroplasty is sometimes done in conjunction with a **vagotomy** procedure in which the vagus nerves that stimulate stomach acid production and gastric motility (movement) are cut. This may delay gastric emptying and pyloroplasty will help correct that effect.

## Diagnosis

Diagnosis begins with an accurate history of prior illnesses and existing medical conditions as well as a family history of ulcers or other gastrointestinal (stomach and intestines) disorders. A complete history and comprehensive diagnostic testing may include:

- location, frequency, duration, and severity of pain
- vomiting and description of gastric material
- bowel habits and description of stool
- all medications, including over-the-counter products
- appetite, typical diet, and weight changes
- family and social stressors
- alcohol consumption and smoking habits

- heart rate, pulse, and blood pressure
- chest examination and x ray, if necessary
- palpation (pressing with the hands) of the abdomen
- rectal examination and stool testing
- pelvic examination in sexually active females
- examination of testicles and inguinal (groin) area in males
- testing for the presence of *Helicobacter pylori*
- complete blood count and blood chemistry profile
- urinalysis
- imaging studies of gastrointestinal system (x ray, other types of scans)
- biopsy of stomach lining using a tube-like telescopic instrument (endoscope)

## Preparation

Before surgery, standard preoperative blood and urine tests will be performed and various x rays may be ordered. The patient will not be permitted to eat or drink anything after midnight the night before the procedure. When the patient is admitted to the hospital, cleansing enemas may be ordered to empty the intestine. If nausea or vomiting are present, a suction tube may be used to empty the stomach.

## Aftercare

The patient will spend several hours in a recovery area after surgery where blood pressure, pulse, respiration, and temperature will be monitored. The patient's breathing may be shallower than normal because of the effect of anesthesia and the patient's reluctance to breathe deeply and experience pain at the site of the surgical incision. The patient will be shown how to support the site while breathing deeply or coughing, and will be given pain medication as needed. Fluid intake and output will be measured. The operative site will be observed for any sign of redness, swelling, or wound drainage. Intravenous fluids are usually given for 24–48 hours until the patient is gradually permitted to eat a special light diet and as bowel activity resumes. About eight hours after surgery, the patient may be allowed to walk a little, increasing movement gradually over the next few days. The average hospital stay, dependent upon the patient's overall recovery status and any underlying conditions, ranges from six to eight days.

## Risks

Potential complications of this abdominal surgery include excessive bleeding, surgical wound infection, incisional hernia, recurrence of gastric ulcer, chronic

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

A pyloroplasty surgery is performed by a general surgeon in a hospital or medical center operating room.

diarrhea, and malnutrition. After the surgery, the surgeon should be informed of an increase in pain, and of any swelling, redness, drainage, or bleeding in the surgical area. The development of headache, muscle aches, dizziness, fever, abdominal pain or swelling, constipation, nausea or vomiting, rectal bleeding, or black stools should also be reported.

### Normal results

Complete healing is expected without complications. Recovery and a return to normal activities should take from four to six weeks.

### Morbidity and mortality rates

Successful treatment of *Helicobacter pylori* has improved morbidity and mortality rates, and the prognosis for PUD, with proper treatment and avoidance of causative factors, is excellent. Pyloroplasty is rarely performed in primary ulcer disease. Morbidity and mortality are higher in patients with secondary ulcers because of underlying illness that complicates both PUD and surgical treatment.

## QUESTIONS TO ASK THE DOCTOR

- How will this surgery be performed?
- What is your experience with this procedure? How often do you perform this procedure?
- Why must I have the surgery?
- What are my options if I opt not have the surgery?
- How can I expect to feel after surgery?
- What are the risks involved in having this surgery?
- How quickly will I recover? When can I return to school or work?
- What are my chances of getting this condition again?
- What can I do to avoid getting this condition again?

## Quadrantectomy

### Definition

Quadrantectomy is a surgical procedure in which a “quadrant” (approximately one-fourth) of the breast, including tissue surrounding a cancerous tumor, is removed. It is also called a partial or segmental **mastectomy**.

### Purpose

Quadrantectomy is a type of breast-conserving surgery used as a treatment for breast cancer. Prior to the advent of breast-conserving surgeries, total mastectomy (complete removal of the breast) was considered the standard surgical treatment for breast cancer. Procedures such as quadrantectomy and **lumpectomy** (removing the tissue directly surrounding the tumor) have allowed doctors to treat cancer without sacrificing the entire affected breast.

### Demographics

The American Cancer Society estimates that approximately 211,300 new cases of breast cancer are diagnosed annually in the United States, and 39,800 women die as a result of the disease. Approximately one in eight women will develop breast cancer at some point in her life. The risk of developing breast cancer increases with age: women ages 30–40 have a one in 252 chance; ages 40–50 have a one in 68 chance; ages 50–60 have a one in 35 chance; and ages 60–70 have a one in 27 chance.

In the 1990s, the incidence of breast cancer was higher among white women (113.1 cases per 100,000 women) than African American women (100.3 per 100,000). The **death** rate associated with breast cancer, however, was higher among African American women (29.6 per 100,000) than Caucasian women (22.2 per 100,000). Rates were lower among Hispanic women

(14.2 per 100,000), Native American women (12.0), and Asian women (11.2 per 100,000).

### Description

The patient is usually placed under **general anesthesia** for the duration of the procedure. In some instances, a local anesthetic may be administered with sedation to help the patient relax.

During quadrantectomy, a margin of normal breast tissue, skin, and muscle lining is removed around the periphery of the tumor. This decreases the risk of any abnormal cells being left behind and spreading locally or to other parts of the body (a process called metastasis). The amount removed is generally about one-fourth of the size of the breast (hence, the “quadrant” in quadrantectomy). The remaining tissue is then reconstructed to minimize any cosmetic defects, and then sutured closed. Temporary drains may be placed through the skin to remove excess fluid from the surgical site.

Some patients may have the lymph nodes removed from under the arm (called the axillary lymph nodes) on the same side as the tumor. Lymph nodes are small, oval- or bean-shaped masses found throughout the body that act as filters against foreign materials and cancer cells. If cancer cells break away from their primary site of growth, they can travel to and begin to grow in the lymph nodes first, before traveling to other parts of the body. Removal of the lymph nodes is therefore a method of determining if a cancer has begun to spread. To remove the nodes, a second incision is made in the area of the armpit and the fat pad that contains the lymph nodes is removed. The tissue is then sent to a pathologist, who extracts the lymph nodes from the fatty tissue and examines them for the presence of cancer cells.

### Diagnosis/Preparation

Breast tumors may be found during self-examination or an examination by a health care professional. In

## KEY TERMS

**Mammogram**—A set of x rays taken of the front and side of the breast; used to diagnose various abnormalities of the breast.

**Pathologist**—A medical doctor who specializes in the diagnosis of diseases from the microscopic analyses of cells and tissues.

other cases, they are visualized during a routine mammogram. Symptoms such as breast pain, changes in breast size or shape, redness, dimpling, or irritation may be an indication that medical attention is warranted.

Prior to surgery, the patient is instructed to refrain from eating or drinking after midnight on the night before the operation. The physician will tell the patient what will take place during and after surgery, as well as expected outcomes and potential complications of the procedure.

## Aftercare

The patient may return home the same day or remain in the hospital for one to two days after the procedure. Discharge instructions will include how to care for the incision and drains, what activities to restrict (i.e., driving and heavy lifting), and how to manage post-operative pain. Patients are often instructed to wear a well-fitting support bra for at least a week following surgery. A follow-up appointment to remove **stitches** and drains is usually scheduled 10–14 days after surgery.

If lymph nodes are removed, specific steps should be taken to minimize the risk of developing lymphedema of the arm, a condition in which excess fluid is not properly drained from body tissues, resulting in chronic swelling. This swelling can sometimes become severe enough to interfere with daily activity. Prior to being discharged, the patient will learn how to care for the arm, and how to avoid infection. She will also be told to avoid sunburn, refrain from heavy lifting, and to be careful not to wear tight jewelry and elastic bands.

Most patients undergo radiation therapy as part of their complete treatment plan. The radiation usually begins immediately or soon after quadrantectomy, and involves a schedule of five days of treatment a week for five to six weeks. Other treatments, such as chemotherapy or hormone therapy, may also be prescribed depending on the size and stage of the patient's cancer.

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

Quadrantectomy is usually performed by a general surgeon, breast surgeon, or surgical oncologist. Radiation therapy is administered by a radiation oncologist, and chemotherapy by a medical oncologist. The surgical procedure is frequently done in a hospital setting (especially if lymph nodes are to be removed at the same time), but specialized outpatient facilities are sometimes preferred.

## Risks

Risks associated with the surgical removal of breast tissue include bleeding, infection, breast asymmetry, changes in sensation, reaction to the anesthesia, and unexpected scarring.

Some of the risks associated with removal of the lymph nodes include excessive bleeding, infection, pain, excessive swelling, and damage to nerves during surgery. Nerve damage may be temporary or permanent, and may result in weakness, numbness, tingling, and drooping. Lymphedema is also a risk whenever lymph nodes have been removed; it may occur immediately following surgery or months to years later.

## Normal results

Most patients will not experience recurrences of the cancer following a treatment plan of quadrantectomy and radiation therapy. One study followed patients for a period of 20 years after breast-conserving surgery, and found that only 9% experienced recurrence of the cancer.

## Morbidity and mortality rates

Following removal of the axillary lymph nodes, there is approximately a 10% risk of lymphedema and a 20% risk of abnormal skin sensations. Approximately 17% of women undergoing breast-conserving surgery have a poor cosmetic result (e.g., asymmetry or distortion of shape). The risk of complications associated with general anesthesia is less than 1%.

## Alternatives

A full mastectomy, in which the entire affected breast is removed, is one alternative to quadrantectomy. A **simple mastectomy** removes the entire breast, while a radical mastectomy removes the entire breast

## QUESTIONS TO ASK THE DOCTOR

- Why is quadrantectomy recommended?
- What methods of anesthesia and pain relief will be used?
- Where will the incision be located, and how much tissue will be removed?
- Will a lymph node dissection be performed?
- Is sentinel node biopsy appropriate in this case?
- Is postsurgical radiation therapy recommended?

plus parts of the chest muscle wall and the lymph nodes. In terms of recurrence and survival rates, breast-conserving surgery has been shown to be equally effective as mastectomy in treating breast cancer.

A new technique that may eliminate the need for removing many axillary lymph nodes is called sentinel node biopsy. When lymph fluid moves out of a region, the “sentinel” lymph node is the first node it reaches. The theory behind **sentinel lymph node biopsy** is that if cancer is not present in the sentinel node, it is unlikely to have spread to other nearby nodes. This procedure may allow individuals with early stage cancers to avoid the complications associated with partial or radical removal of lymph nodes if there is little or no chance that cancer has spread to them.

## Radical neck dissection

### Definition

Radical neck dissection is a surgical operation used to remove cancerous tissue in the head and neck.

### Purpose

The purpose of radical neck dissection is to remove lymph nodes and other structures in the head and neck that are likely or known to be malignant. Variations on neck dissections exist, depending on the extent of the cancer. A radical neck dissection removes the most tissue. It is performed when the cancer has spread widely in the neck. A modified neck dissection removes less tissue, and a selective neck dissection even less.

### Demographics

Experts estimate that there are approximately 5,000–10,000 radical neck dissections in the United States each year. Men and women undergo radical neck dissections at about the same rate.

### Description

Cancers of the head and neck (sometimes inaccurately called throat cancer) often spread to nearby tissues and into the lymph nodes. Removing these structures is one way of controlling the cancer.

Of the 600 lymph nodes in the body, approximately 200 are in the neck. Only a small number of these are removed during a neck dissection. In addition, other structures such as muscles, veins, and nerves may be removed during a radical neck dissection. These include the sternocleidomastoid muscle (one of the muscles that functions to flex the head), internal jugular (neck) vein, submandibular gland

(one of the salivary glands), and the spinal accessory nerve (a nerve that helps control speech, swallowing, and certain movements of the head and neck). The goal is always to remove all the cancer, but to save as many components surrounding the nodes as possible.

An incision is made in the neck, and the skin is pulled back (retracted) to reveal the muscles and lymph nodes. The surgeon is guided in what to remove by tests performed prior to surgery and by examination of the size and texture of the lymph nodes.

### Diagnosis/Preparation

This operation should not be performed if cancer has metastasized (spread) beyond the head and neck, or if the cancer has invaded the bones of the cervical vertebrae (the first seven bones of the spinal column) or the skull. In these cases, the surgery will not effectively contain the cancer.

Radical neck dissection is a major operation. Extensive tests are performed before the operation to try to determine where and how far the cancer has spread. These may include lymph node biopsies, computed tomography (CT) scans, **magnetic resonance imaging** (MRI) scans, and barium swallows. In addition, standard preoperative blood and **liver function tests** are performed, and the candidate will meet with an anesthesiologist before the operation. The candidate should tell the anesthesiologist about all drug allergies and all medication (prescription, non-prescription, or herbal) that are presently being taken.

### Aftercare

A person who has had a radical neck dissection will stay in the hospital several days after the operation, and sometimes longer if surgery to remove the primary tumor was performed at the same time. Drains are inserted under the skin to remove the fluid that accumulates in the neck area. Once the drains are removed

**Major veins and arteries in the neck.** (Illustration by Electronic Illustrators Group.)

and the incision appears to be healing well, people are usually discharged from the hospital, but will require follow-up doctor visits. Depending on how many structures are removed, a person who has had a radical neck dissection may require physical therapy to regain use of the arm and shoulder.

### Risks

The greatest risk in a radical neck dissection is damage to the nerves, muscles, and veins in the neck. Nerve damage can result in numbness (either temporary or permanent) to different regions on the neck and loss of function (temporary or permanent) to

parts of the neck, throat, and shoulder. The more extensive the neck dissection, the more function a person is likely to lose. As a result, it is common following radical neck dissection for people to have stooped shoulders, limited ability to lift one or both arms, and limited head and neck rotation and flexion due to the removal of nerves and muscles. Other risks are the same as for all major surgery: potential bleeding, infection, and allergic reaction to anesthesia.

### Normal results

Normal lymph nodes are small and show no cancerous cells under a microscope. Abnormal lymph

**Major muscles of the neck.** (Illustration by Electronic Illustrators Group.)

nodes may be enlarged and show malignant cells when examined under a microscope.

### Morbidity and mortality rates

The mortality rate for radical neck dissection can be as high as 14%.

Morbidity rates are somewhat higher and are due to bleeding, post-surgery infection, and medicine errors.

### Alternatives

Alternatives to radical neck dissection depend on the reason for the proposed surgery. Most alternatives

are far less acceptable. Radiation and chemotherapy may be used instead of a radical neck dissection in the case of cancer. Alternatives for some surgical procedures may reduce scarring, but are not as effective in the removal of all pathological tissue. Chemotherapy and radiation or altered fractionated radiotherapy are reasonable alternatives.

### Resources

#### BOOKS

- Braunwald, E., D. L. Longo, and J. L. Jameson. *Harrison's Principles of Internal Medicine*, 15th Edition. New York: McGraw Hill, 2001.

## KEY TERMS

**Barium swallow**—Barium is used to coat the throat to highlight the tissues lining the throat, allowing them to be visualized using x-ray pictures.

**Computed tomography (CT or CAT) scan**—Using x rays taken from many angles and computer modeling, CT scans help locate and estimate the size of tumors and provide information on whether they can be surgically removed.

**Lymph nodes**—Small, bean-shaped collections of tissue found in lymph vessels. They produce cells and proteins that fight infection and filter lymph. Nodes are sometimes called lymph glands.

**Lymphatic system**—Primary defense against infection in the body; the tissues, organs, and channels (similar to veins) that produce, store, and transport lymph and white blood cells to fight infection.

**Magnetic resonance imaging (MRI)**—Uses magnetic fields and computers to create detailed cross-sectional pictures of the interior of the body.

**Malignant**—Cancerous. Cells tend to reproduce without normal controls on growth and form tumors or invade other tissues.

**Metastasize**—Spread of cells from the original site of a cancer to other parts of the body where secondary tumors are formed.

Reconstructive surgery see **Plastic, reconstructive, and cosmetic surgery**

## QUESTIONS TO ASK THE DOCTOR

- What tests will be performed to determine if the cancer has spread?
- Which parts of the neck will be removed?
- How will a radical neck dissection affect daily activities after recovery?
- What is the likelihood that all of the cancer can be removed with a radical neck dissection?
- Are the involved lymph nodes on one or both sides of the neck?
- What will be the resulting appearance after surgery?
- How will my speech and breathing be affected?
- Is the surgeon board certified in otolaryngology head and neck surgery?
- How many radical neck procedures has the surgeon performed?
- What is the surgeon's complication rate?

## Recovery at home

### Definition

Recovery at home after surgery may require certain dietary and environmental restrictions, recommended rest and limitations to physical activities, and other required or restricted activities as recommended by a physician or surgeon.

### Purpose

Postoperative recovery at home should promote physical healing and rest and recovery from the stress of surgery. For patients who undergo **orthopedic surgery**, the home recovery period will also involve rehabilitation to regain diminished musculoskeletal functioning. Emotional and psychological recovery from life-altering surgeries may also begin during the home recovery period.

### Description

When patients are discharged from either an ambulatory surgical facility or a hospital, they will receive written instructions from their physician containing restrictions, requirements, and recommendations for their postoperative recovery at home. A nurse will usually review these instructions verbally with the patient and answer any questions and concerns. They may also

call one or up to several days after a surgical discharge to follow up on how the patient is feeling and answer any questions about home recovery.

Restrictions and recommendations outlined in home recovery instructions may include:

- **Driving restrictions.** A patient may be prohibited from driving for a period of time due to functional limitations or to medication that impairs driving ability.
- **Work restrictions.** Depending on the nature of the patient's job, he or she may be required to stay home from work or request alternate duties until recovery is complete.
- **Social restrictions.** Patients at high risk of complications from infection, such as an organ transplant patient, may be advised to avoid anyone with a cold or flu and to stay away from crowds or social gatherings during the initial recovery period.
- **Medication recommendations.** Prescription and/or over the counter drugs may be recommended on an as-needed basis for pain and nausea. Other drugs may also be required.
- **Dietary limitations.** Certain types of gastrointestinal procedures and other surgeries may require a restricted diet during the recovery period. Alcohol may also be prohibited, particularly if pain medication has been prescribed.
- **Ambulation recommendations.** The doctor will note if the patient should refrain from lifting heavy objects, climbing stairs, having sex, or participating in other potentially strenuous activities.
- **Exercise recommendations.** If movement, stretches, or exercise is encouraged as part of recovery, that fact will also be noted.
- **Incision care.** Patients are instructed on how to care for their incision and educated on signs of infection (i.e., redness, warmth, swelling, fever, odor).
- **Home care needs.** Some patients may require a visiting nurse or live-in health aide for a period of time as they recover from surgery.
- **Adaptive equipment.** Assistive or adaptive devices such as crutches, a walker, prosthetics, or bed or bathroom hand rails may be necessary.
- **Follow-up with physician.** A patient may be instructed to call the doctor's office to schedule a follow-up appointment. The patient should also be given criteria for warning signs and symptoms that may occur with the procedure, and when to call the physician if the symptoms appear.
- **Other required medical appointments.** If a patient has undergone orthopedic surgery or another procedure that requires rehabilitation, he or she may need

## KEY TERMS

**Ambulation**—To walk or move from place to place.

**Ambulatory care**—An outpatient facility; designed for patients who do not require inpatient hospital treatment or care.

**Prosthetics**—A custom-built artificial limb or other body part.

**Orthopedic**—Related to the musculoskeletal system, including the bones, joints, muscles, ligaments, and tendons.

to see a physical or occupational therapist to regain range of motion, strength, and mobility. Depending on the type of surgery performed, the expertise of other medical professionals may also be required.

The postoperative period is also a time of emotional healing. Patients who face a long recovery and rehabilitation may feel depressed or anxious about their situation. Providing a patient with realistic goals and expectations for recovery both before and after the surgery can help avoid feelings of failure or let down when things do not progress as quickly as the patient had hoped. Realistic recovery expectations can also prevent a patient from doing too much too early and potentially hindering the healing process.

Certain life-altering surgeries, such as an **amputation** or a **mastectomy**, carry their own set of emotional issues. Counseling, therapy, or participation in a patient support group may be an important part of postoperative recovery as a patient adjusts to the new post-surgical life.

## Preparation

Discharge recommendations for home recovery are typically explained to the patient before he or she is allowed to leave the hospital or ambulatory care facility. In some cases, the patient may be required to sign paperwork indicating that he or she has both received and understood **home care** instructions.

Depending on the surgical procedure undergone, a patient may be taught some home care techniques while still in the hospital. Physical therapy exercises, **incision care**, and use of assistive devices such as crutches or splints are a few self-care skills that may be demonstrated and practiced in an inpatient environment.

A physical and emotional support system is a crucial part of a successful home recovery. Faced with restrictions to movement, driving, and possibly

more, a patient needs someone at home to help with the daily tasks of independent living. If family or friends are not nearby or available, a visiting nurse or home healthcare aide should be hired before the patient is discharged to home recovery.

## Normal results

Following home care instructions can help to speed a patient's recovery time and ensure the safe resumption of normal activities. In some cases, the familiar, comforting home environment may even speed the healing process or improve the degree of recovery. One study of patients 64 and older undergoing hip surgery found that patients who were allowed to undergo rehabilitation at home had significantly better outcomes than those who underwent rehabilitation as hospital inpatients. On average, the former had better physical capacity and independent living skills when assessed six months after surgery.

Some studies have also indicated that gender may have an impact on the success and speed of postoperative home recovery. Some studies have found that women recover more rapidly than men. However, animal and laboratory studies have found that progesterone and estrogen may be involved in the period immediately after surgery or injury. This would indicate that women may have a natural advantage in recovery. Scientists continue to study the recovery process to try to understand it and help patient recovery as quickly and completely as possible.

## Recovery room

### Definition

The recovery room, also called a post-anesthesia care unit (PACU), is a space a patient is taken to after surgery to safely regain consciousness from anesthesia and receive appropriate **postoperative care**.

### Description

Patients who have had surgery or diagnostic procedures requiring anesthesia or sedation are taken to the recovery room, where their **vital signs** (e.g., pulse, blood pressure, temperature, blood oxygen levels) are monitored closely as the effects of anesthesia wear off. The patient may be disoriented when he or she regains consciousness, and the recovery room nursing staff will work to ease their anxiety and ensure their physical and emotional comfort.

The recovery room staff will pay particular attention to the patient's respiration, or breathing, as the patient recovers from anesthesia. A **pulse oximeter**, a clamp-like device that attaches to a patient's finger and uses infrared light to measure the oxygen saturation level of the blood, is usually used to assess respiratory stability. If the oxygen saturation level is too low, supplemental oxygen may be administered through a nasal cannula or face mask. Intravenous fluids are also frequently administered in the recovery room.

Because **general anesthesia** can cause a patient's core **body temperature** to drop several degrees, retaining body heat to prevent hypothermia and encourage good circulation is also an important part of recovery room care. Patients may be wrapped in blankets warmed in a heater or covered with a forced warm-air blanket system to bring body temperature back up to normal. They may also receive heated intravenous fluids.

The amount of time a patient requires in the recovery room will vary by surgical or diagnostic procedure and the type of anesthesia used. As the patient recovers from anesthesia, their postoperative condition is assessed by the recovery room nursing staff. A physician may order analgesic or antiemetic medication for any

## KEY TERMS

**Fast track**—A protocol for postoperative patients with projected shorter recovery times. Fast-tracking a patient means that they will either bypass PACU completely, or spend a shorter time there with less intensive staff intervention and monitoring.

**Hypothermia**—Low core body temperature of 95°F (35°C) or less.

**Nasal cannula**—A piece of flexible plastic tubing with two small clamps that fit into the nostrils and provide supplemental oxygen flow.

pain or nausea and vomiting, and the surgeon and/or anesthesiologist may come by to examine the patient.

Both hospitals and ambulatory surgical centers have recovery room facilities, which are generally located in close proximity to the **operating room**. A recovery room may be private, or it may be a large, partitioned space shared by many patients. Each patient bay, or space, is equipped with a variety of medical monitoring equipment. To keep the area sterile and prevent the spread of germs, outside visitors may be required to don a gown and cap or may be prohibited completely. Spouses or partners of women who are recovering after caesarean section and the parents of children recovering from surgery are typically excluded from any visitor prohibitions in the recovery room. In fact, parents are usually encouraged to be with their child in recovery to minimize any emotional trauma.

In some ambulatory surgery facilities, patients may have a different postoperative experience if they receive short-acting anesthetic drugs for their procedure. This protocol, known as "fast tracking," involves either shortening the time spent in the PACU or, if clinically indicated, bypassing the PACU altogether and sending the patient directly to what is known as a phase II step-down unit. A step-down unit is a transitional care area where patients can rest and recover before discharge with a lesser degree of monitoring and staff attention than in a PACU.

### Normal results

After the effects of anesthesia have worn off completely and the patient's condition is considered stable, he or she will either be returned to their hospital room (for inpatient surgery) or discharged (for **outpatient surgery**). Patients who are discharged will be briefed on postoperative care instructions to follow at home before they are released.

## Rectal prolapse repair

### Definition

Rectal prolapse repair surgery treats a condition in which the rectum falls, or prolapses, from its normal anatomical position because of a weakening in the surrounding supporting tissues.

### Purpose

A prolapse occurs when an organ falls or sinks out of its normal anatomical place. The pelvic organs normally have tissue (muscle, ligaments, etc.) holding them in place. Certain factors, however, may cause those tissues to weaken, leading to prolapse of the organs. The rectum is the last out of six divisions of the large intestine; the anus is the opening from the rectum through which stool exits the body. A complete rectal prolapse occurs when the rectum protrudes through the anus. If rectal prolapse is present, but the rectum does not protrude through the anus, it is called occult rectal prolapse, or rectal intussusception. In females, a rectocele occurs when the rectum protrudes into the posterior (back) wall of the vagina.

Factors that are linked to the development of rectal prolapse include age, repeated childbirth, constipation, ongoing physical activity, heavy lifting, prolapse of other pelvic organs, and prior **hysterectomy**. Symptoms of rectal prolapse include protrusion of the rectum during and after defecation, fecal incontinence (inadvertent leakage of feces with physical activity), constipation, and rectal bleeding. Women may

## KEY TERMS

**Perineum**—The area between the vagina and anus in females, and the scrotum and anus in males.

experience a vaginal bulge, vaginal pressure or pain, painful sexual intercourse, and lower back pain.

### Demographics

The overall incidence of rectal prolapse in the United States is approximately 4.2 per 1,000 people. The incidence of the disorder increases to 10 per 1,000 among patients older than 65. Most patients with rectal prolapse are women; the ratio of male-to-female patients is one to six.

### Description

Surgery is generally not performed unless the symptoms of the prolapse have begun to interfere with daily life. Because of the numerous defects that can cause rectal prolapse, there are more than 50 operations that may be used to treat the condition. A perineal or abdominal approach may be used. While abdominal surgery is associated with a higher rate of complications and a longer recovery time, the results are generally longer lasting. Perineal surgery is generally used for older patients who are unlikely to tolerate the abdominal procedure well.

### Abdominal and laparoscopic approach

Rectopexy and anterior resection are the two most common abdominal surgeries used to treat rectal prolapse. The patient is usually placed under **general anesthesia** for the duration of surgery. During rectopexy, an incision into the abdomen is made, the rectum isolated from surrounding tissues, and the sides of the rectum lifted and fixed to the sacrum (lower back-bone) with **stitches** or with a non-absorbable mesh. Anterior resection removes the S-shaped sigmoid colon (the portion of the large intestine just before the rectum); the two cut ends are then reattached. This straightens the lower portion of the colon and makes it easier for stool to pass. Rectopexy and anterior resection may also be performed in combination and may lead to a lower rate of prolapse recurrence.

As an alternative to the traditional laparotomy (large incision into the abdomen), laparoscopic surgery may be performed. **Laparoscopy** is a surgical procedure in which a laparoscope (a thin, lighted tube) and various instruments are inserted into the

abdomen through small incisions. Rectopexy and anterior resection have been performed laparoscopically with good results. A patient's recovery time following laparoscopic surgery is shorter and less painful than following traditional abdominal surgery.

### *Perineal approach*

Perineal repair of rectal prolapse involves a surgical approach around the anus and perineum. The patient may be placed under general or regional anesthesia for the duration of surgery.

The most common perineal repair procedures are the Altemeier and Delorme procedures. During the Altemeier procedure (also called a proctosigmoidectomy), the prolapsed portion of the rectum is resected (removed) and the cut ends reattached. The weakened structures supporting the rectum may be stitched into their anatomical position. The Delorme procedure involves the resection of only the mucosa (inner lining) of the prolapsed rectum. The exposed muscular layer is then folded and stitched up and the cut edges of mucosa stitched together.

A rarely used procedure is anal encirclement. Also called the Thiersch procedure, anal encirclement involves the insertion of a thin circular band of non-absorbable material under the skin of the anus. This narrows the anal opening and prevents the protrusion of the rectum through the opening. This procedure, however, does not address the underlying condition and therefore is generally reserved for patients who are not good candidates for more invasive surgery.

## Diagnosis/Preparation

**Physical examination** is most often used to diagnose rectal prolapse. The patient is asked to strain as if defecating; this increase in intra-abdominal pressure will maximize the degree of prolapse and aid in diagnosis. In some instances, imaging studies such as defecography (x rays taken during the process of defecation) may be administered to determine the extent of prolapse.

Before surgery, an intravenous (IV) line is placed so that fluid and/or medications may be easily administered to the patient. A Foley catheter will be placed to drain urine. **Antibiotics** are usually given to help prevent infection. The patient will be given a bowel prep to cleanse the colon and prepare it for surgery.

## Aftercare

A Foley catheter may remain for one to two days after surgery. The patient will be given a liquid diet

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

Rectal prolapse repair is usually performed in a hospital operating room. The surgery may be performed by a general surgeon, a colon and rectal surgeon (who focuses on diseases of the colon, rectum, and anus), or a gastrointestinal surgeon (who focuses on diseases of the gastrointestinal system).

until normal bowel function returns. The recovery time following perineal repair is faster than recovery after abdominal surgery and usually involves a shorter hospital stay (one to three days following perineal surgery, three to seven days following abdominal surgery). The patient will be instructed to avoid activities for several weeks that will cause strain on the surgical site; these include lifting, coughing, long periods of standing, sneezing, straining with bowel movements, and sexual intercourse. High-fiber foods should be gradually added to the diet to avoid constipation and straining that could lead to prolapse recurrence.

## Risks

Risks associated with rectal prolapse surgery include potential complications associated with anesthesia, infection, bleeding, injury to other pelvic structures, recurrent prolapse, and failure to correct the defect. Following a resection procedure, a leak may occur at the site where two cut ends of colon are reattached, requiring surgical repair.

## Normal results

Most patients undergoing rectal prolapse repair will be able to return to normal activities, including work, within four to six weeks after surgery. The majority of patients will experience a significant improvement in symptoms and have a low chance of prolapse recurrence if heavy lifting and straining is avoided.

## Morbidity and mortality rates

The approximate recurrence rates for the most commonly performed surgeries as reported by several studies are as follows:

- Altemeier procedure: 5–54%
- Delorme procedure: 5–26%
- anal encirclement: 25%
- rectopexy: 2–10%

## QUESTIONS TO ASK THE DOCTOR

- What defect is causing the rectal prolapse?
- What surgical procedure is recommended for treatment?
- What are the risks and complications associated with the recommended procedure?
- Are any non-surgical treatment alternatives available?
- How soon after surgery may normal activities be resumed?

- anterior resection: 7–9%
- rectopexy with anterior resection: 0–4%

Abdominal surgeries are associated with a higher rate of complications than perineal repairs; rectopexy, for example, has a morbidity rate of 3–29%, and anterior resection a rate of 15–29%. The complication rate for combined rectopexy and anterior resection is slightly lower at 4–23%. Approximately 25% of patients undergoing anal encirclement will eventually require surgery to treat complications associated with the procedure.

### Alternatives

There are currently no medical therapies available to treat rectal prolapse. In cases of mild prolapse where the rectum does not protrude through the anus, a high-fiber diet, stool softeners, enemas, or **laxatives** may help to avoid constipation, which may make the prolapse worse.

## Rectal resection

### Definition

A rectal resection is the surgical removal of a portion of the rectum.

### Purpose

Rectal resections repair damage to the rectum caused by diseases of the lower digestive tract, such as cancer, **diverticulitis**, and inflammatory bowel disease (ulcerative colitis and Crohn's disease). Injury, obstruction, and ischemia (compromised blood supply) may require rectal resection. Masses and scar tissue can grow within the rectum, causing blockages that prevent normal elimination of feces. Other diseases, such as diverticulitis and ulcerative colitis, can cause perforations in the rectum. Surgical removal of the damaged area can return normal rectal function.

### Demographics

Colorectal cancer affects 140,000 people annually, causing 60,000 deaths. Incidence of the disease in 2001 differed among ethnic groups, with Hispanics having 10.2 cases per 100,000 people and African Americans having 22.8 cases per 100,000. Rectal cancer incidence is a portion of the total colorectal incidence rate. Surgery is the optimal treatment for rectal cancer, resulting in cure in 45% of patients. Recurrence due to surgical failure is low, from 4–8%, when the procedure is meticulously performed.

Crohn's disease and ulcerative colitis, both chronic inflammatory diseases of the colon, each affect approximately 500,000 young adults. Surgery is recommended when medication fails patients with ulcerative colitis. Nearly three-fourths of all Crohn's patients will require surgery to remove a diseased section of the intestine or rectum.

## Rectal resection

A tumor in the rectum or lower colon can be removed by a rectal resection (A). An incision is made around the patient's anus (B). The tumor is pulled down through the incision (C). An attached area of the colon is also removed (D). The area is repaired, leaving an opening for bowel functioning (E). (Illustration by GGS Information Services. Cengage Learning, Gale.)

## KEY TERMS

**Adjuvant therapy**—Treatment used to increase the effectiveness of surgery, usually chemotherapy or radiation used to kill any cancer cells that might be remaining.

**Anastomosis**—The surgical connection of two sections of tubes, ducts, or vessels.

**Diverticuli**—Pouches in the intestinal wall usually created from a diet low in fiber.

**Enema**—Insertion of a tube into the rectum to infuse fluid into the bowel and encourage a bowel movement. Ordinary enemas contain tap water, mixtures of soap and water, glycerine and water, or other materials.

**Intestine**—Commonly called the bowels, divided into the small and large intestine. They extend from the stomach to the anus. The small intestine is about 20 ft (6 m) long. The large intestine is about 5 ft (1.5 m) long.

**Ischemia**—A compromise in blood supply delivered to body tissues that causes tissue damage or death.

**Sigmoid colon**—The last third of the intestinal tract that is attached to the rectum.

## Description

During a rectal resection, the surgeon removes the diseased or perforated portion of the rectum. If the diseased or damaged section is not very large, the separated ends are reattached. Such a procedure is called rectal anastomosis.

## Diagnosis/Preparation

### Diagnostic tests

A number of tests identify masses and perforations within the intestinal tract.

- A lower GI (gastrointestinal) series is a series of x rays of the colon and rectum that can help identify ulcers, cysts, polyps, diverticuli (pouches in the intestine), and cancer. The patient is given a barium enema to coat the intestinal tract, making disease easier to see on the x rays.
- Flexible sigmoidoscopy involves insertion of a sigmoidoscope, a flexible tube with a miniature camera, into the rectum to examine the lining of the rectum and the sigmoid colon, the last third of the intestinal

tract. The sigmoidoscope can also remove polyps or tissue for biopsy.

- A colonoscopy is similar to the flexible sigmoidoscopy, except the flexible tube examines the entire intestinal tract.
- Magnetic resonance imaging (MRI), used both prior to and during surgery, allows physicians to determine the precise margins for the resection, so that all of the diseased tissue can be removed. This also identifies patients who could most benefit from adjuvant therapy such as chemotherapy or radiation.

### Preoperative preparation

To cleanse the bowel, the patient may be placed on a restricted diet for several days before surgery, then placed on a liquid diet the day before, with nothing by mouth after midnight. A series of enemas and/or oral preparations (GoLytely, Colyte, or senna) may be ordered to empty the bowel. Oral anti-infectives (neomycin, erythromycin, or kanamycin sulfate) may be ordered to decrease bacteria in the intestine and help prevent post-operative infection. The operation can be done with an abdominal incision (laparotomy) or using minimally invasive techniques with small tubes to allow insertion of the operating instruments (**laparoscopy**).

### Aftercare

**Postoperative care** involves monitoring blood pressure, pulse, respiration, and temperature. Breathing tends to be shallow because of the effect of the anesthesia and the patient's reluctance to breathe deeply due to discomfort around the surgical incision. The patient is taught how to support the incision during deep breathing and coughing, and given pain medication as necessary. Fluid intake and output is measured, and the wound is observed for color and drainage.

Fluids and electrolytes are given intravenously until the patient's diet can be resumed, starting with liquids, then adding solids. The patient is helped out of bed the evening of the surgery and allowed to sit in a chair. Most patients are discharged in two to four days.

### Risks

Rectal resection has potential risks similar those of other major surgeries. Complications usually occur while the patient is in the hospital and the patient's general health prior to surgery will be an indication of the risk potential. Patients with heart problems and stressed immune systems are of special concern. Both

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

Rectal resections are performed by general surgeons and colorectal surgeons as in-patient surgeries under general anesthesia.

during and following the procedure, the physician and nursing staff will monitor the patient for:

- excessive bleeding
- wound infection
- thrombophlebitis (inflammation and blood clot in the veins in the legs)
- pneumonia
- pulmonary embolism (blood clot or air bubble in the lungs' blood supply)
- cardiac stress due to allergic reaction to the general anaesthetic

Symptoms that the patient should report, especially after discharge, include:

- increased pain, swelling, redness, drainage, or bleeding in the surgical area
- flu-like symptoms such as headache, muscle aches, dizziness, or fever
- increased abdominal pain or swelling, constipation, nausea or vomiting, or black, tarry stools

### Normal results

Complete healing is expected without complications. The recovery rate varies, depending on the patient's overall health prior to surgery. Typically, full recovery takes six to eight weeks.

### Morbidity and mortality rates

Mortality has decreased from nearly 28% to under 6%, through the use of prophylactic **antibiotics** before and after surgery.

### Alternatives

If the section of the rectum to be removed is very large, the rectum may not be able to be reattached. Under those circumstances, a **colostomy** would be preformed. The distal end of the rectum would be closed and left to atrophy. The proximal end would be brought through an opening in the abdomen to create an opening, a stoma, for feces to be removed from the body.

## QUESTIONS TO ASK THE DOCTOR

- Am I a good candidate for laparoscopic surgery?
- What kinds of preoperative tests will be required?
- What medications will be given for pain relief after the surgery?
- What will I need to do to prepare for surgery?
- What will my recovery time be and what restrictions will I have?

## Red blood cell indices

### Definition

Red blood cell (RBC) indices are calculations derived from the **complete blood count** that aid in the diagnosis and classification of anemia.

### Purpose

Red blood cell indices help classify types of anemia, a decrease in the oxygen carrying capacity of the blood. Healthy people have an adequate number of correctly sized red blood cells containing enough

hemoglobin to carry sufficient oxygen to all the body's tissues. Anemia is diagnosed when either the hemoglobin or **hematocrit** of a blood sample is too low.

### Description

Measurements needed to calculate RBC indices are the red blood cell count, hemoglobin, and hematocrit. The hematocrit is the percentage of blood by volume that is occupied by the red cells. The three main RBC indices are:

- **Mean corpuscular volume (MCV).** The average size of the red blood cells expressed in femtoliters (fl). MCV is calculated by dividing the hematocrit (as percent) by the RBC count in millions per microliter of blood, then multiplying by 10.
- **Mean corpuscular hemoglobin (MCH).** The average amount of hemoglobin inside an RBC expressed in picograms (pg). The MCH is calculated by dividing the hemoglobin concentration in grams per deciliter by the RBC count in millions per microliter, then multiplying by 10.
- **Mean corpuscular hemoglobin concentration (MCHC).** The average concentration of hemoglobin in the RBCs expressed as a percent. It is calculated by dividing the hemoglobin in grams per deciliter by the hematocrit, then multiplying by 100.

The mechanisms by which anemia occurs will alter the RBC indices in a predictable manner. Therefore, the RBC indices permit the physician to narrow down the possible causes of an anemia. The MCV is an index of the size of the RBCs. When the MCV is below normal, the RBCs will be smaller than normal and are described as microcytic. When the MCV is elevated, the RBCs will be larger than normal and are termed macrocytic. RBCs of normal size are termed normocytic.

Failure to produce hemoglobin results in smaller than normal cells. This occurs in many diseases, including iron deficiency anemia, thalassemia (an inherited disease in which globin chain production is deficient), and anemias associated with chronic infection or disease. Macrocytic cells occur when division of RBC precursor cells in the bone marrow is impaired. The most common causes of macrocytic anemia are vitamin B<sub>12</sub> deficiency, folate deficiency, and liver disease. Normocytic anemia may be caused by decreased production (e.g. malignancy and other causes of bone marrow failure), increased destruction (hemolytic anemia), or blood loss. The RBC count is low, but the size and amount of hemoglobin in the cells are normal.

### KEY TERMS

**Anemia**—A variety of conditions in which a person's blood cannot carry as much oxygen as is needed by the tissues.

**Hypochromic**—A descriptive term applied to a red blood cell with a decreased concentration of hemoglobin.

**Macrocytic**—A descriptive term applied to a larger than normal red blood cell.

**Mean corpuscular hemoglobin (MCH)**—A calculation of the average weight of hemoglobin in a red blood cell.

**Mean corpuscular hemoglobin concentration (MCHC)**—A calculation of the average concentration of hemoglobin in a red blood cell.

**Mean corpuscular volume (MCV)**—A measure of the average volume of a red blood cell.

**Microcytic**—A descriptive term applied to a smaller than normal red blood cell.

**Normochromic**—A descriptive term applied to a red blood cell with a normal concentration of hemoglobin.

**Normocytic**—A descriptive term applied to a red blood cell of normal size.

**Red cell distribution width (RDW)**—A measure of the variation in the size of red blood cells.

A low MCH indicates that cells have too little hemoglobin. This is caused by deficient hemoglobin production. Such cells will be pale when examined under the microscope and are termed hypochromic. Iron deficiency is the most common cause of a hypochromic anemia. The MCH is usually elevated in macrocytic anemias associated with vitamin B<sub>12</sub> and folate deficiency.

The MCHC is the ratio of hemoglobin mass in the RBC to cell volume. Cells with too little hemoglobin are lighter in color and have a low MCHC. The MCHC is low in microcytic, hypochromic anemias such as iron deficiency, but is usually normal in macrocytic anemias. The MCHC is elevated in hereditary spherocytosis, a condition with decreased RBC survival caused by a structural protein defect in the RBC membrane.

Cell indices are usually calculated from tests performed on an automated electronic cell counter. However, these counters measure the MCV, which is directly proportional to the voltage pulse produced

as each cell passes through the counting aperture. Electronic cell counters calculate the MCH, MCHC, hematocrit, and an additional parameter called the red cell distribution width (RDW).

The RDW is a measure of the variance in red blood cell size. It is calculated by dividing the standard deviation (a measure of variation) of RBC volume by the MCV and multiplying by 100. A large RDW indicates abnormal variation in cell size, termed anisocytosis. The RDW aids in differentiating anemias that have similar indices. For example, thalassemia minor and iron deficiency anemia are both microcytic and hypochromic anemias, and overlap in MCV and MCH. However, iron deficiency anemia has an abnormally wide RDW, but thalassemia minor does not.

### Diagnosis/Preparation

RBC indices require 3–5 mL of blood collected by vein puncture with a needle. A nurse or phlebotomist usually collects the sample.

### Aftercare

Discomfort or bruising may occur at the puncture site. Pressure to the puncture site until the bleeding stops reduces bruising; warm packs relieve discomfort. Some people feel dizzy or faint after blood has been drawn and should be allowed to lie down and relax until they are stable.

### Risks

Other than potential bruising at the puncture site, and/or dizziness, there are no complications associated with this test. However, certain prescription medications may affect the test results. These drugs include zidovudine (Retrovir), phenytoin (Dilantin), and azathioprine (Imuran). When the hematocrit is determined by centrifugation, the MCV and MCHC may differ from those derived by an electronic cell counter, especially in anemia. Plasma trapped between the RBCs tends to cause an increase in the hematocrit, giving rise to a somewhat higher MCV and lower MCHC.

### Normal results

Normal results for red blood cell indices are as follows:

- MCV: 80–96 fL
- MCH: 27–33 pg
- MCHC: 33–36%
- RDW: 12–15%

## Reoperation

### Definition

Reoperation is a term used by surgeons for the duplication of a surgical procedure. Repeating surgery may involve surgery at the same site, at another site for the same condition, or to repair a structure that was treated in a previous surgery.

### Purpose

Success for most surgical procedures depends, in large part, upon the lack of a need to repeat the surgery. However, failure of some feature of a procedure may be only one of many reasons that reoperation is necessary. Reasons for repeat surgery depend upon surgical skills, as well as the reason for the primary surgery. Some diseases and conditions necessitate or make probable repeating the operation.

### Cancer

Surgeries for cancer are sometimes repeated because a new tumor or more surrounding tissue has been affected by the original malignancy. This is often the case with breast surgery for cancer that involves breast conservation management. Often it is necessary to re-excise the site of the previously biopsied primary cancer. In the case of breast cancer, only 50% of re-excision specimens show residual tumor. If cancer cell

## KEY TERMS

**Reoperation**—The repeat of a surgical procedure required for a variety of reasons, from surgical failure, replacement of failed component parts, or treatment of progressive disease.

**Surgical revision**—The failure of a procedure, which requires surgery be performed to improve the result.

are found with the re-excision, this may change the treatment protocol. Colon cancer sometimes involves more surgeries to resect newly affected areas beyond the previous primary site.

### *Coronary artery surgery*

Currently, about 10% of coronary artery procedures are reoperations due to the progression of the disease into native vessels between operations, as well as to treat diseased vein grafts. The mortality associated with reoperation is significantly higher than that of the original bypass procedures. In one study, patients undergoing their first coronary artery bypass graft (CABG) had a mortality rate of 1.7% versus 5.2% for elective reoperation.

### *Orthopedic surgeries*

Arthroplasty—the operative restoration of a joint like the elbow, knee, hip, or shoulder, often involves components that need repair. Infections of the joint may also require reoperation with the complete removal of all prostheses and cement. Re-implantation is repeated after a six-week course of **antibiotics**. Other bone surgeries that have a high reoperation rate are back surgeries, including spinal surgeries involving discectomy in which discs are fused together to reduce pain. Due to scarring or infection, there may be a need for reoperation. As the frequency of repeat back surgeries increases, the chance of a satisfactory result drops precipitously.

### *Gastrointestinal surgeries*

Crohn's disease surgeries are often repeated. Operations that cut and stitch only the area of obstruction, called stricturoplasty, often have repeat operations if the affected area is the small intestine. Another gastrointestinal surgery that often requires reoperation is fundoplication or flap wrapping of the lower part of the esophagus to prevent the reflux of acid from the stomach back into the esophagus. Folding

the loose valve above the stomach in such a way as to tighten its ability to close treats the condition known as gastroesophageal reflux disease (GERD). The surgery has a high failure rate of between 30% after five years and 63% after 10 years. Reoperation may be required because of surgical failure, breakdown of tissue, injury to nearby organs, or an excessively wrapped fundus that leads to trouble swallowing.

### *Vasectomy and penile prostheses*

These surgeries often have complications that lead to reoperation, largely due to surgical failure.

## Normal results

In general, reoperation is more difficult and involves more risks than the original procedure. It requires more operative time; more blood is lost; and the incidences of infection and clots are higher. Advancements in design and improvements in cementing techniques for component failure in **arthroplasty** have improved the results of reoperation.

## Retinal cryopexy

### Definition

Retinal cryopexy, also called retinal **cryotherapy**, is a procedure that uses intense cold to induce a chorioretinal scar and to destroy retinal or choroidal tissue.

## Purpose

The retina is the very thin membrane in the back of the eye that acts like the “film” in a camera. It is held against the inside back portion of the eye by pressure from fluid within the eye. In the front part of the eye, the retina is firmly attached at a ring just behind the lens called the pars plana. In the back part of the eye, the retina is continuous with the optic nerve. In between the pars plana and the optic nerve the retina has no fixed attachments. The retina collects information from the images projected on it from the eye lens and sends it along the optic nerve to the brain, where the information is interpreted and experienced as sight.

Several disorders can affect the retina and retinal cryopexy is used to treat the following conditions:

- retinal breaks or detachments
- retinal ischemia (retinal tissue that lacks oxygen)
- neovascularization (proliferation of blood vessels in the retina)
- Coats’ disease (abnormal retinal blood vessels that cause loss of vision)
- retinoblastoma (intraocular tumors)

## Demographics

Disease and disorders affecting the retina cause the majority of the visual disability and blindness in the United States. Retinal detachment occurs in one in 10,000 Americans each year, with middle-aged and older individuals being at higher risk than the younger population. Coats’ disease usually affects children, especially boys, in the first 10 years of life, but it can also affect young adults. The condition affects central vision, typically in only one eye. Severity can range from mild vision loss to total retinal detachment and blindness. No cause has yet been identified for Coats’ disease. According to the National Cancer Institute, retinoblastoma accounts for approximately 11% of cancers developing in the first year of life, and for 3% of the cancers developing among children younger than 15 years. In the United States, approximately 300 children and adolescents below the age of 20 are diagnosed with retinoblastoma each year. The majority of cases occur among young children, with 63% of all retinoblastoma occurring before the age of two years.

## Description

Usually, retinal cryopexy is administered under **local anesthesia**. The procedure involves placing a metal probe against the eye. When a foot pedal is depressed, the tip of the cryopexy probe becomes

## KEY TERMS

**Chorioretinal**—Relating to the choroid coat of the eye and retina.

**Choroid**—Middle layer of the eye, between the retina and sclera.

**Coats’ disease**—Also called exudative retinitis, a chronic abnormality characterized by the deposition of cholesterol on the outer retinal layers.

**Ophthalmoscope**—An instrument for viewing the interior of the eye, particularly the retina. Light is thrown into the eye by a mirror (usually concave) and the interior is then examined with or without the aid of a lens.

**Retina**—Light-sensitive layer of the eye.

**Retinoblastoma**—Malignant tumor of the retina.

**Sclera**—The tough white outer coat of the eyeball.

very cold as a result of the rapid expansion of very cold gases (usually nitrous oxide) within the probe tip. When the probe is placed on the eye, the formation of water crystals followed by rapid thawing results in tissue destruction. This is followed by healing and scar tissue formation.

In the case of retinal detachment, treatment calls for irritating the tissue around each of the retinal tears. Cryopexy stimulates scar formation, sealing the edges of the tear. This is typically done by looking into the eye using the indirect ophthalmoscope while pushing gently on the outside of the eye using the cryopexy probe, producing a small area of freezing that involves the retina and the tissues immediately underneath it. Using multiple small freezes like this, each of the tears is surrounded. Irritated tissue forms a scar, which brings the retina back into contact with the tissue underneath it.

## Diagnosis/Preparation

The earlier the retinal disorder diagnosis is confirmed, the greater the chance of successful outcome. Diagnosis is based on symptoms and a thorough examination of the retina. An ophthalmoscope is used to examine the retina. This is a small, hand-held instrument consisting of a battery-powered light and a series of lenses that is held up to the eye. The ophthalmologist is able to see the retina and check for abnormalities by shining the light into the eye and looking through the lens. Eye drops are placed in the eyes to dilate the pupils and help visualization. Afterward, an

indirect ophthalmoscope is used. This instrument is worn on the specialist's head, and a lens is held in front of the patient's eye. It allows a better view of the retina. Examination with a slit lamp microscope may also be done. This microscope enables the ophthalmologist to examine the different parts of the eye under magnification. After instilling drops to dilate the pupil, the slit lamp is used to detect retinal tears and detachment. A visual acuity test is also usually performed to assess vision loss. This test involves reading letters from a standard eye chart.

Additional diagnostic procedures are used in the case of Coats' disease and retinoblastoma. Ultrasonography helps in differentiating Coats' disease from retinoblastoma. CT scan may be used to characterize the intraocular features of Coats' disease. MRI is another very useful diagnostic tool used to distinguish retinoblastoma from Coats' disease.

### Aftercare

After the procedure, patients are taken to a **recovery room**, and observed for 30–60 minutes. Tylenol or pain medication is usually given. Healing typically takes 10–14 days. Vision may be blurred briefly, and the operated eye is usually red and swollen for some time following cryopexy. Cold compresses applied to the eyelids relieve some of the discomfort. Most patients are able to walk the day after surgery and are discharged from the hospital within a week. After discharge, patients are advised to gently cleanse their eyelids every morning, and as necessary, using warm tap water and cotton balls or tissues. Day surgery patients are usually allowed to go home two hours after the surgery is complete.

### Risks

Risks involved in retinal cryopexy include infection, perforation of the eye with the anesthetic needle, bleeding, double vision, and glaucoma. All of these complications however, are quite uncommon.

### Normal results

If treated early, the outcome of cryopexy for Coats' disease may be successful in preventing progression and in some cases can improve vision, but this is less effective if the retina has completely detached. For retinal reattachments, the retina can be repaired in about 90% of cases. Early treatment almost always improves the vision of most patients with retinal detachment. Some patients, however, require more than one cryopexy procedure to repair the damage.

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

Retinal cryopexy is performed in the treating physician's office or in a hospital setting depending on the condition motivating the surgery. The physician is usually an ophthalmologist, specialized in the treatment of retinal disorders. An ophthalmologist is a physician who specializes in the medical and surgical care of the eyes and visual system and in the prevention of eye disease and injury. He has completed four or more years of college premedical education, four or more years of medical school, one year of internship, and three or more years of specialized medical and surgical and refractive training and experience in eye care.

### Morbidity and mortality rates

Survival rates for children with retinoblastoma are favorable, with more than 93% alive five years after diagnosis. Males and females have similar five-year survival rates for the period 1976–1994, namely 93 and 94% respectively. African American children had slightly lower survival rates (86%) than Caucasian children (94%).

### Alternatives

Several alternatives to retinal cryopexy are available, depending on the condition being treated. A few examples include:

- **Laser photocoagulation.** This type of surgery induces a therapeutic effect by destroying outer retinal tissue, thus reducing the oxygen requirements of the retina, and increasing oxygen delivery to the remaining retina through alterations in oxygen diffusion from the choroid. It is used for repairing retinal tears.
- **Pneumatic retinopexy.** This procedure is used to reattach retinas. After numbing the eye with a local anesthesia, the surgeon injects a small gas bubble into the inside of the eye. The bubble presses against the retina, flattening it against the back wall of the eye. Since the gas rises, this treatment is most effective for detachments located in the upper portion of the eye.
- **Scleral buckle.** With this technique, a tiny sponge or silicone band is attached to the outside of the eye, pressing inward and holding the retina in position. After removing the vitreous gel from the eye

## QUESTIONS TO ASK THE DOCTOR

- How is retinal cryopexy performed?
- Why is the surgery required?
- Will my vision improve?
- What are the risks of retinal cryopexy?
- Is the procedure painful?
- How long will it take to recover from the surgery?
- How much retinal cryopexies do you perform each year?

(vitrectomy), the surgeon seals a few areas of the retina into position with laser or cryotherapy.

- Radiation therapy. For neuroblastomas, this treatment uses high-energy radiation to kill or shrink cancer cells.
- Chemotherapy. Another alternative for neuroblastoma. Chemotherapy uses drugs to kill cancer cells. The drugs are delivered through the bloodstream, and spread throughout the body to the cancer site.

## Retropubic suspension

### Definition

Retropubic suspension refers to the surgical procedures used to correct incontinence by supporting and stabilizing the bladder and urethra. The Burch procedure, also known as retropubic urethropexy procedure or Burch colosuspension, and Marshall-Marchetti-Krantz procedure (MMK) are the two primary surgeries for treating stress incontinence. The major difference between these procedures is the method for supporting the bladder. The Burch procedure uses sutures to attach the urethra and bladder to muscle tissue in the pelvic area. MMK uses sutures to attach these organs to the pelvic cartilage. Laparoscopic retropubic surgery can be performed with a video laparoscope through small incisions in the belly button and above the pubic hairline.

### Purpose

The urinary system expels a quart and a half of urine per day. The amount of urine produced depends upon diet and medications taken, as well as **exercise** and loss of water due to sweating. The ureters, two tubes connecting the kidneys and the bladder, pass urine almost continually and when the bladder is full the brain sends a signal to the bladder to relax and let urine pass from the bladder to the urethra. People who are continent control the release of urine from the urethra via the sphincter muscles. These two sets of muscles act like rubber bands to keep the bladder closed until a conscious decision is made to urinate. The intrinsic sphincter or urethral sphincter muscles

**Weak pelvic floor muscles (A) can cause stress incontinence. In a retropubic suspension, the neck of the bladder is elevated and stitched to the pubic bone to hold it in place (B).** (Illustration by GGS Information Services. Cengage Learning, Gale.)

keep the bladder closed and the extrinsic sphincter muscles surround the urethra and prevent leakage. Incontinence is common when either the urethra lacks tautness and stability (genuine stress urine incontinence, SUI) and/or the sphincter muscles are unable to keep the bladder closed (intrinsic sphincter deficiency, ISD).

Incontinence occurs in many forms with four primary types related to anatomic, neurological, and dietary causes; or disease and injury.

### *Stress incontinence*

The most frequent form of incontinence is stress incontinence. This relates to leakage of the urethra with activity that puts stress on the abdominal muscles. The primary sign of stress incontinence is this leakage at sneezing, coughing, exercise, or other straining activities, which indicates a lack of support for the urethra due to weakened muscles, fascia, or ligaments. Pressure from the abdomen with movement, like exercising, uncompensated by tautness or stability in the urethra, causes the urethra to be displaced or mobile leading to leakage. Essentially, this hypermobility of the urethra is an indication that it is moving down or herniating through weakened pelvic structures.

To diagnose incontinence and determine treatment, three grades of severity for stress incontinence are used.

- Type I: Moderate movement of the urethra, with no hernia or cystocele.

- Type II: Severe or hypermobility in the urethra of more than 0.8 in (2 cm), with or without decent of the urethra into pelvic structures.
- Type III: Hypermobility of the urethra where the primary source of incontinence is the inability of the sphincter muscles to keep the bladder closed. This is due to weakness or deficiency in the intrinsic sphincter muscles.

### *Urge incontinence*

Urge incontinence relates to the frequent need to urinate and may involve going to the bathroom every two hours. Accidents are common when not reaching a bathroom in time. Urge incontinence is not due to general changes in the urethra or supporting muscles. It is often linked to other disorders that produce muscle spasms in the bladder, such as infections. Urge incontinence can also be due to underlying illnesses like stroke, spinal cord injury, multiple sclerosis and Alzheimer's disease, which cause detrusor hyperflexia—the contracting of the bladder muscle responsible for sending urine from the bladder to the urethra. Urge incontinence is very common in the elderly, especially those in long term care facilities.

### *Mixed incontinence*

Mixed incontinence is a combination of stress incontinence and urge incontinence, especially in older women. Since each form of incontinence pertains to different

## KEY TERMS

**Genuine urinary stress incontinence (USI)**—Stress incontinence due to hypermobility of the urethra.

**Intrinsic sphincter deficiency (ISD)**—A factor in severe stress incontinence due to the inadequacy of the sphincter muscles to keep the bladder closed.

**Retropubic urethropexy**—A generic term for the Burch procedure and its variants that treat mild stress incontinence by stabilizing the urethra with retropubic surgery.

**Stress incontinence**—Leakage of urine upon movements that put pressure on the abdominal muscles such as coughing, sneezing, laughing, or exercise. One of four types of incontinence.

**Urethra hypermobility**—Main factor in stress urinary incontinence, with severity based upon how far the urethra has descended into the pelvic floor through herniation or cystocele.

functions or anatomy, it is very important to distinguish which part of the incontinence is to be treated by surgery.

### *Overflow incontinence*

Overflow incontinence results in leakage from a bladder that never completely empties due to weakened bladder muscles. Overflow incontinence is involuntary and not accompanied by the urge to urinate. Many causes exist for overflow incontinence, including weak bladder muscles due to diabetes, nerve damage, or a blocked urethra. Men are more frequently affected than women.

### Demographics

Over 15 million Americans have urinary incontinence and women comprise 85% of all cases. It affects 25% of women of reproductive age and 50% of women past menopause. Due to the female anatomy, women have twice the risk for stress incontinence compared to men. In addition, childbirth places pressure and burden on the pelvic muscles that often weaken with age, thereby weakening urethra stability. Women are more prone to surgeries for urological changes than men and severe urinary incontinence is often associated with these surgeries as well as hysterectomies. The majority of women with incontinence have stress incontinence or mixed incontinence. Male incontinence occurs primarily in response to blockage in the prostate or after prostate

surgery. It is usually treated with implants and/or an artificial sphincter insert.

### Description

There are a variety of retropubic suspension surgeries available to treat stress incontinence. The variations differ by the types of structures used to support the urethra and bladder. In all procedures, parts of the pelvic anatomy (pubic bone, ligaments) serve as an anchor or wall upon which the urethra is tacked for stability. The surgery is called a suspension surgery because it stabilizes the urethra from tilting by suspending it against a part of the pelvic anatomy. The Burch procedure is often performed when other surgery is needed such as repair of the urethra for cystoceles and urethral reconstruction. However, this procedure is the most difficult of the anti-incontinent surgeries and is more common in mild forms of stress incontinence where intrinsic sphincter deficiency is not present.

The Burch procedure can be done through open abdominal surgery, which requires a long incision at the bikini line, or surgery performed through the vagina. The patient, in stirrups, receives **general anesthesia**. Within the retropubic area, the anterior vaginal wall is separated from the bladder manually. The bladder neck is identified and old adhesions or fatty tissues are removed. The neck of the bladder is sutured to pubic ligaments where it will form adhesions and thereby gain stability. The surgeon examines for bladder injury and the surgery is completed. Urethral position is tested by placing a cotton-tipped swab in the urethra and measuring the angle. With abdominal surgery or vaginal surgery a catheter may be put in place by the surgeon for postoperative voiding and to decrease the risks of infection. A suction drain may be placed in the retropubic space for bleeding. The drain is removed one to three days after surgery.

Recently, laparoscopic surgery has been used to perform retropubic suspensions. Laparoscopic surgery requires only three or four 0.25-inch (0.6-cm) incisions in the belly button, pubic hairline, or groin area and uses small instruments without opening the abdominal cavity. A shorter healing time is seen with this procedure. the hospital stay is usually not more than 24 hours and recovery to normal activities takes about seven to 14 days. However, the Burch procedure performed using laparoscopic techniques requires great skill on the part of the surgeon and research indicates that the results may not be as long lasting as those developed with abdominal or vaginal surgery.

## Diagnosis/Preparation

A patient with incontinence may have multiple factors that induce transient or chronic incontinence. It is crucial that the physician obtain a complete history, physical, clinical, neurological and medication evaluation of the patient, as well as a radiographic assessment before continuing urological tests aimed at a surgical solution. The specific indications for the Burch colosuspension procedure or its variants is the correction of stress urinary incontinence. This can be a patient who also requires abdominal surgery that cannot be performed vaginally, like **hysterectomy** or sigmoid surgery, as well as patients who have SUI without ISD.

A urodynamic study with a point pressure leak test will allow a diagnosis to be made that can distinguish the patient who has a hypermobile urethra from the patient who also has ISD. The point pressure leak test, also known as the Valsalva leak test, measures the amount of abdominal pressure required to induce leakage. The patient is asked to cough or strain in order to encourage leakage. The point at which the patient leaks helps determine if stress incontinence with ISD contribution is present. Obese patients and patients that engage in high impact exercise regimens are not considered good candidates for retropubic suspension.

## Aftercare

Patients with open retropubic procedures are given pain medication postoperatively that is tapered down over the next two days. A suprapubic catheter stays in place for approximately five days with voiding difficulties encountered initially in many patients. Patients with laparoscopic suspensions are reported to have less blood loss during surgery, less postoperative narcotic requirements, and shorter hospital stays. Patients are expected to refrain from strenuous activity for three months and to have a follow-up visit within three weeks after surgery.

## Risks

As with any major abdominal or pelvic surgical procedures, complications that may occur after a retropubic suspension include bleeding; injury to the bladder, urethra, and ureters; wound infection; and blood clots. Specific to the Burch procedure are complications that involve urethral obstruction because of urethral kinking due to elevation of the vagina or bladder base. Postoperative voiding difficulties are common and depend upon the suture tension of the urethral axis. Corrective surgery and the release of the

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

Retropubic suspension procedures are performed by a urological surgeon specially trained in incontinence surgeries. Surgery is performed in a general hospital.

urethra to a more anatomic position resolves voiding issues with a very high rate of success. Vaginal prolapse is also a risk of this procedure.

## Normal results

The patient can expect more than 80–90% cure or great improvement in their incontinence. There is a large body of literature documenting the success of the Burch procedure. Published research shows a cure rate ranging from 63% to 93%, according to the actual version of colosuspension used. Laparoscopic surgery has not produced the long term results that open surgery has and there is the possibility that the fibrosis (adhesion) necessary for a successful outcome does not occur as easily with the laparoscopic procedure. Patients not carefully screened out for ISD will not have a high level of success with the Burch procedure since the source of the incontinence will not have been treated. Sling procedures are recommended for patients with ISD instead of colosuspension surgery.

## Morbidity and mortality rates

The Burch procedure may aggravate vaginal wall weakness or vaginal prolapse. This incident varies between 3% and 17%. Research on the Marshall-Marchetti-Krantz procedure pertaining to 2,712 patients found a complication rate of 21%, with wound complications and infections making up the majority, 5.5% and 3.9% respectively. Direct wound injury occurred in 1.6% and obstructions in 0.3% overall.

## Alternatives

General or simple severe stress incontinence related primarily to weakening of the urethral support can be remedied with changes in diet, weight loss, and certain behavioral and rehabilitative measures. These include:

- Regular, daily exercising of the pelvic muscles called Kegel exercises, requiring 30–200 contractions a day for eight weeks.

## QUESTIONS TO ASK THE DOCTOR

Which retropubic suspension procedure is recommended?

What is your cure rate with this procedure?

What is your injury rate for this procedure?

Could my incontinence be treated just as well with the sling procedure?

Do you perform laparoscopic surgeries to treat incontinence?

- Biofeedback to gain awareness and control of pelvic muscles.
- Vaginal weight training in which small weights are inserted in the vagina to tighten vaginal muscles.
- Mild electrical stimulation to increase contractions in pelvic muscles.
- Bladder retraining in which the patient is taught how to resist the urge to urinate and expand the intervals between urinations.

There are also medications that can facilitate continence for those experiencing stress or urge incontinence. These include some kinds of antidepressants, although the mechanism of action is not quite understood, as well as antispasmodic medication and estrogen therapy. Finally, should behavioral, rehabilitative, and surgical procedures fail, there remain alternatives through the use of vaginal cones and urethral plugs that can be inserted and removed by the patient.

Nancy McKenzie, PhD

## Rh blood typing

### Definition

Rh blood typing is performed in order to determine the Rh factor of an individual's blood. The term "Rh factor" refers to an antigen on the surface of the red blood cells. All red blood cells have certain substances on their surfaces. These substances are called "antigens," and may be molecules of protein, carbohydrate, glycolipid, or glycoprotein. Blood typing categorizes blood by identifying the presence or absence of these antigens on the surface of the red blood cell.

The Rh system identifies the presence (denoted as positive) or absence (denoted as negative) of a particular antigen termed the Rhesus antigen. Its names stems from the fact that the Rh factor was first

identified on the red blood cell surfaces of Rhesus monkeys. When the Rh factor is present on the surface of the red blood cell, the blood is said to be Rh-positive; when the Rh factor is absent from the surface of the red blood cell, the blood is said to be Rh-negative.

The Rh factor status is reported in conjunction with identification of the major ABO blood group of the individual. The ABO blood group system identifies a type of protein antigen on the red blood cell surface as Type A, Type B, Type AB, or Type O. An individual's blood type, then is reported as a combination of information obtained about the ABO and RH blood group systems; for example, A-positive, or A-negative, etc.

Blood typing is particularly important when an individual needs to receive a blood **transfusion**. If the wrong blood type is given, there is a high risk of an adverse transfusion reaction. For example, the first time an Rh-negative individual is given blood from an Rh-positive donor, there will probably not be any problem. However, if the Rh-negative individual receives future transfusions of Rh-positive blood, the recipient's immune system will recognize the Rh antigen on the donor blood as foreign, and will begin to produce antibodies directed against that antigen. The antibodies will attack the donor blood, damaging and bursting the donor red blood cells. This results in high serum levels of hemoglobin spilling from the burst red blood cells (called hemoglobinemia), disseminated intravascular coagulation or DIC (a condition in which clotting factors are used up very rapidly, resulting in the potential for severe, uncontrollable bleeding), kidney failure, and eventually complete cardiovascular collapse (a combination of heart attack, shock, and lack of blood flow to all major organs and tissues).

Knowing a pregnant woman's Rh-factor is crucial because there is always a chance during pregnancy, labor, and delivery, that some of the baby's blood will get into the mother's bloodstream. If this happens in an Rh-negative mother with an Rh-positive baby, the mother's body will identify the baby's Rh-negative blood as foreign and begin producing antibodies against the Rh-factor. This is called Rh-sensitization. The first time this sensitization occurs between a mother and her baby, the baby usually doesn't suffer any ill-effects. But in subsequent pregnancies, if the mother is again carrying an Rh-positive baby, having already been exposed to the Rh-antigen previously, her body will begin to produce Rh-antibodies more quickly and in greater numbers. If these cross over into the baby's bloodstream, they can begin destroying the

baby's red blood cells, resulting in severe illness. This problem is referred to as Rh disease, hemolytic disease of the newborn, or erythroblastosis fetalis. In order to avoid this problem, Rh testing is done prior to pregnancy or early in pregnancy. Rh-negative women can be given a special shot called Rh-immune globulin which can prevent Rh-sensitization.

### Purpose

Blood typing is ordered prior to a blood transfusion, to make sure that the donor blood type is appropriately compatible with the recipient's blood type. It is also done on donor blood, on a donor who is giving an organ to be used for transplantation, as well as prior to surgery (so that the patient's blood type is known, should the individual needs an unexpected, emergency blood transfusion). Rh-typing is also important in pregnant women. When the mother and the baby have different Rh-types, there is a risk to the baby of illness caused by the mother's antibodies; if the mother is identified as having Rh-negative blood, a shot called Rh-immune globulin can prevent the problem from developing.

### Precautions

Some situations may confuse the results of blood typing, including recent x-ray test using contrast, use of medications such as methyl dopa, levodopa, and certain **antibiotics** (including cephalixin). Other factors that may confuse test results include having received a blood transfusion in the previous three months, having had a bone marrow transplant in the past, or having a history of cancer or leukemia.

### Description

This test requires blood to be drawn from a vein (usually one in the forearm), generally by a nurse or phlebotomist (an individual who has been trained to draw blood). A tourniquet is applied to the arm above the area where the needle stick will be performed. The site of the needle stick is cleaned with antiseptic, and the needle is inserted. The blood is collected in vacuum tubes. After collection, the needle is withdrawn, and pressure is kept on the blood draw site to stop any bleeding and decrease bruising. A bandage is then applied.

### Preparation

There are no restrictions on diet or physical activity, either before or after the blood test.

## KEY TERMS

**Disseminated intravascular dissemination**—A condition in which the clotting factors in the blood are rapidly used up, resulting in a severe deficit in clotting factors and a very high risk of severe, uncontrollable bleeding.

**Erythroblastosis fetalis**—A condition in which the incompatibility between a mother's Rh-negative blood type and a baby's Rh-positive blood type results in destruction of the baby's red blood cells by maternal antibodies.

## Aftercare

As with any blood tests, discomfort, bruising, and/or a very small amount of bleeding is common at the puncture site. Immediately after the needle is withdrawn, it is helpful to put pressure on the puncture site until the bleeding has stopped. This decreases the chance of significant bruising. Warm packs may relieve minor discomfort. Some individuals may feel briefly woozy after a blood test, and they should be encouraged to lie down and rest until they feel better.

## Risks

Basic blood tests, such as Rh blood typing, do not carry any significant risks, other than slight bruising and the chance of brief dizziness.

## Results

Rh blood typing reports back whether the individual's red blood cells have the Rh antigen present on their surface (Rh-positive) or absent from their surface (Rh-negative). About 84% of all people are Rh-positive; about 16% are Rh-negative.

## Rheumatoid factor testing

### Definition

Rheumatoid factor is a type of antibody. Antibodies, also called immunoglobulins, are proteins produced by the body. Antibodies work to clear the body of potentially threatening infections or substances, fighting off various invaders, such as viruses, bacteria, toxins, mold spores, etc.

The body's immune system is made up of lymphoid organs, including lymph nodes, the bone marrow (located within the center of long bones) and the thymus (located in the chest). These lymphoid organs produce lymphocytes, including T cells and B cells. These lymphocytes circulate within the bloodstream, within the lymph system, and are also positioned in clumps within organs and on mucosal surfaces of the body. When a B cell encounters a foreign invader, it recognizes it as foreign by virtue of a chemical identifier on its surface (called an antigen). Once the B cell recognizes an antigen, the B cell gives rise to a large number of plasma cells. These plasma cells are capable of producing antibodies.

Antibodies are made up of units called "chains." All antibodies are composed of two larger chains (called heavy chains) and two smaller chains (called light chains). The tip of the antibody is referred to as the hypervariable region. This hypervariable region is responsible for unique chemical properties possessed by each antibody that allow a specific antibody to "recognize" and match up to a particular antigen. The combination of an antibody with a specific antigen, creates an antibody-antigen complex, marking the invader as foreign and in need of inactivation or destruction by other immune cells in the body.

The first time an antigen is encountered by the immune system, the body's response is slow. Time is required in order to activate the machinery necessary to produce the very specific type of antibody necessary to combat that antigen. However, if that particular antigen is encountered in the future, the needed machinery is already available, and antibody production in response to a "familiar" antigen is quite rapid.

One of the important attributes of a healthy, well-functioning immune system rests on its ability to distinguish between “self” and “other.” This means that it’s crucial that the antibodies don’t mistakenly identify parts of the body itself as foreign invaders. When this does happen, the body’s immune system attacks the body, damaging and destroying it. Conditions in which this occurs are referred to as autoimmune disorders. One example of an autoimmune disorder is the condition called rheumatoid arthritis or RA. In RA, the lining of the joints (synovium) is mis-recognized by the immune system as foreign, resulting in the immune system creating specific antibodies that repeatedly attack, damage, and destroy the joints’ lining, resulting in the cluster of symptoms that accompany this disease.

Rheumatoid factor belongs to the class of antibodies known as IgM antibodies. IgM antibodies are primarily found in the blood, and comprise about 13% of all antibodies. IgM functions to kill bacteria, and is found in the earlier phases of immune response to bacterial invasion of the bloodstream (bacteremia).

In rheumatoid arthritis, rheumatoid factor is directed against IgG antibodies. IgG antibodies are very common circulating antibodies; in fact, about 80% of all circulating antibodies are IgG. IgG is found in blood and tissue fluids. IgG functions to coat invading particles, marking them so that they can more easily and rapidly be taken up by other types of immune cells. IgG is the predominant antibody cell in the later or secondary phase of the immune response.

When rheumatoid factor encounters IgG, it attaches itself to the IgG, forming an immune complex. This immune complex kicks off a complicated immune cascade, prompting the production and release of a variety of chemicals that ultimately mis-identify the synovium as “non-self,” attack the lining, and over time cause tremendous destruction.

### Purpose

Rheumatoid factor testing is usually done when an individual is having symptoms compatible with an autoimmune disorder, particularly rheumatoid arthritis or Sjogren’s syndrome. Suspicious symptoms include joint stiffness, pain and swelling (especially in the morning), bumps (nodules) under the skin, and/or dry eyes, mouth, and skin.

### Precautions

Rheumatoid factor testing is not diagnostic. This means that getting a specific result does not definitively confirm the presence of any particular disease. Instead, the test is used to correlate with the clinical

## KEY TERMS

**Antibody**—A protein that the body produces in response to exposure to a foreign invader such as a virus, bacteria, fungus, or allergen.

**Antigen**—The protein marker that prompts the body’s immune system to produce antibodies.

**Autoimmune disorder**—A condition in which the body produces antibodies that serve to attack organs or tissues of the body itself.

**Immune system**—The collection of organs, tissues, and cells that serve to protect the body against foreign invaders, such as bacteria, viruses, and fungi.

**Lymphocyte**—A white blood cell; part of the immune system responsible for the production of antibodies.

**Plasma cell**—The specific type of white blood cell that produces antibodies.

**Rheumatoid arthritis**—A condition in which the immune system damages and destroys the synovial lining of the joints. Red, warm, swollen, stiff joints are a common symptom. Over time, other organ systems may also be affected, including the heart, eyes, lungs, and kidneys.

**Sjögren’s syndrome**—A disease in which the immune system damages and destroys exocrine glands, such as those that produce tears and saliva. Dry eyes and mouth are the usual initial symptoms of this disorder, but other organ systems can also be severely affected over time, including the skin, pancreas, liver, lungs, brain, and kidneys.

picture, meaning the history and the symptoms that an individual is experiencing.

Some situations may confuse the results of testing for rheumatoid factor, including very high blood levels of triglycerides or other fats, or advanced age (people over 65 years of age have a higher chance of having a higher-than-normal rheumatoid factor that is not associated with disease).

### Description

This test requires blood to be drawn from a vein (usually one in the forearm), generally by a nurse or phlebotomist (an individual who has been trained to draw blood). A tourniquet is applied to the arm above the area where the needle stick will be performed. The site of the needle stick is cleaned with antiseptic, and the needle is inserted. The blood is collected in vacuum

tubes. After collection, the needle is withdrawn, and pressure is kept on the blood draw site to stop any bleeding and decrease bruising. A bandage is then applied.

### Preparation

There are no restrictions on diet or physical activity, either before or after the blood test.

### Aftercare

As with any blood tests, discomfort, bruising, and/or a very small amount of bleeding is common at the puncture site. Immediately after the needle is withdrawn, it is helpful to put pressure on the puncture site until the bleeding has stopped. This decreases the chance of significant bruising. Warm packs may relieve minor discomfort. Some individuals may feel briefly woozy after a blood test, and they should be encouraged to lie down and rest until they feel better.

### Risks

Basic blood tests, such as rheumatoid factor testing, do not carry any significant risks, other than slight bruising and the chance of brief dizziness.

### Results

Normal rheumatoid factor results would demonstrate a rheumatoid factor titer less than 1:20-1:40, or a rheumatoid factor of less than 43 nephelometry units.

The patient's, history, symptoms, and rheumatoid factor results are used together in order to arrive at a diagnosis. An elevated rheumatoid factor may indicate the possibility of rheumatoid arthritis or Sjogren's syndrome. However, some patients (about 20%) with these diseases do not have an elevated rheumatoid factor, or have the condition for several years before their rheumatoid factor becomes abnormally elevated.

Rheumatoid factor may also be elevated in a number of other autoimmune conditions, such as systemic lupus erythematosus, vasculitis, or scleroderma; in severe infections such as syphilis or tuberculosis, mononucleosis, malaria, hepatitis, or endocarditis; in certain types of cancer, including leukemia; and in a number of other conditions, such as cirrhosis of the liver, and lung or kidney disease.

## Rhinoplasty

### Definition

The term rhinoplasty means “nose molding” or “nose forming.” It refers to a procedure in **plastic surgery** in which the structure of the nose is changed. The change can be made by adding or removing bone or cartilage, grafting tissue from another part of the body, or implanting synthetic material to alter the shape of the nose.

### Purpose

Rhinoplasty is most often performed for cosmetic reasons. A nose that is too large, crooked, misshapen, malformed at birth, or deformed by an injury can be given a more pleasing appearance. If breathing is impaired due to the form of the nose or to an injury, it can often be improved with rhinoplasty.

### Demographics

Rhinoplasty is the third most common cosmetic procedure among both men and women. Total number of rhinoplasty procedures in the United States in 1999 was 133,058. More than 13,100 of those procedures were performed on men.

### Description

The external nose is composed of a series of inter-related parts that include the skin, the bony pyramid, cartilage, and the tip of the nose, which is composed of cartilage and skin. The strip of skin separating the nostrils is called the columella.

## Rhinoplasty

During an open rhinoplasty, an incision is made in the skin between the nostrils (A). Closed rhinoplasty involves only incisions inside the nose. Rhinoplasty may involve a change in nostril width (B) or removal of a hump on the nose (C) using bone sculpting. After surgery, a splint supports the nose (D), and a cold compress reduces swelling (E). (Illustration by GGS Information Services. Cengage Learning, Gale.)

## KEY TERMS

**Cartilage**—Firm supporting tissue that does not contain blood vessels.

**Columella**—The strip of skin running from the tip of the nose to the upper lip, which separates the nostrils.

**Septum**—The dividing barrier in the center of the nose.

Surgical approaches to nasal reconstruction are varied. Internal rhinoplasty involves making all incisions from inside the nasal cavity. The external, or “open,” technique involves a skin incision across the base of the nasal columella. An external incision allows the surgeon to expose the bone and cartilage more fully and is most often used for complicated procedures. During surgery, the surgeon will separate the skin from the bone and cartilage support. The framework of the nose is then reshaped in the desired form. Shape can be altered by removing or adding bone, cartilage, or skin. The remaining skin is then replaced over the new framework. If the procedure requires adding to the structure of the nose, the donated bone, cartilage, or skin can come from another location on the patient’s body or from a synthetic source.

When the operation is completed, the surgeon will apply a splint to help the bones maintain their new shape. The nose may also be packed, or stuffed with a dressing, to help stabilize the septum.

When a local anesthetic is used, light sedation is usually given first, after which the operative area is numbed. It will remain insensitive to pain for the length of the surgery. A general anesthetic is used for lengthy or complex procedures, or if the doctor and patient agree that it is the best option.

## Diagnosis/Preparation

The quality of the skin plays a major role in the outcome of rhinoplasty. Persons with extremely thick skin may not see a significant change in the underlying bone structure after surgery. On the other hand, thin skin provides almost no cushion to hide many minor bone irregularities or imperfections.

Rhinoplasty should not be performed until the pubertal growth spurt is complete, age 14–15 for girls and older for boys.

During the initial consultation, the candidate and surgeon will determine what changes can be made in

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

Simple rhinoplasty is usually performed in an outpatient surgery center or in the surgeon’s office. Most procedures take only an hour or two, and patients go home right away. Complex procedures may be performed in a hospital and require a short stay.

Rhinoplasty is usually performed by a surgeon with advanced training in plastic and reconstructive surgery.

the shape of the nose. Most doctors take photographs during that consult. The surgeon will also explain the techniques and anesthesia options available to the candidate.

The candidate and surgeon should also discuss guidelines for eating, drinking, smoking, taking or avoiding certain medications, and washing the face for the weeks immediately following surgery.

## Aftercare

Patients usually feel fine immediately after surgery. As a precaution, most surgery centers do not allow patients to drive themselves home after an operation.

The first day after surgery, there will be some swelling of the face. Persons should stay in bed with their heads elevated for at least a day. The nose may hurt and a headache is common. The surgeon will prescribe medication to relieve these conditions. Swelling and bruising around the eyes will increase for a few days, but will begin to diminish after about the third day. Slight bleeding and stuffiness are normal, and vary according to the extent of the surgery performed. Most people are walking in two days, and back to work or school in a week. No strenuous activities are allowed for two to three weeks.

Patients are given a list of postoperative instructions, which include requirements for hygiene, **exercise**, eating, and follow-up visits to the doctor. Patients should not blow their noses for the first week to avoid disruption of healing. It is extremely important to keep the surgical dressing dry. **Dressings**, splints, and **stitches** are removed in one to two weeks. Patients should avoid excessive sun or sunburn.

## QUESTIONS TO ASK THE DOCTOR

Candidates for a rhinoplasty procedure should consider asking the following questions:

- What will be the resulting appearance? (Often, computer programs are available to assist in visualizing the final result.)
- Is the surgeon board certified in plastic and reconstructive surgery?
- How many rhinoplasty procedures has the surgeon performed?
- What is the surgeon's complication rate?
- Will this surgery really make a huge difference to my life or am I trying to live up to an impossible media stereotype of beauty?

### Risks

Any type of surgery carries a degree of risk. There is always the possibility of unexpected events such as an infection or a reaction to the anesthesia.

When the nose is reshaped or repaired from inside, the scars are not visible. If the surgeon needs to make the incision on the outside of the nose, there will be some slight scarring. In addition, tiny blood vessels may burst, leaving small red spots on the skin. These spots are barely visible, but may be permanent.

### Normal results

The best candidates for rhinoplasty are those persons with relatively minor deformities. Nasal anatomy and proportions are quite varied and the final look of any rhinoplasty operation depends on a person's anatomy, as well as the surgeon's skill.

A cosmetic change of the nose will change a person's appearance, but it will not change self-image. A person who expects a different lifestyle after rhinoplasty is likely to be disappointed.

The cost of rhinoplasty depends on the difficulty of the work required and on the specialist chosen. If the problem was caused by an injury, insurance will usually cover the cost. A rhinoplasty done only to change a person's appearance is not usually covered by insurance.

### Morbidity and mortality rates

**Death** from a rhinoplasty procedure is exceedingly rare. When it occurs, the cause is often due to

an adverse reaction to anesthesia or postoperative medications or to an infection. About 10% of persons receiving rhinoplasty require a second procedure.

### Alternatives

The alternative to cosmetic rhinoplasty is to accept oneself, literally, at face value. Persons contemplating rhinoplasty may want to question some of the conventional standards of beauty and work on their body image issues to improve their self-confidence.

## Rhizotomy

### Definition

Rhizotomy is the cutting of nerve roots as they enter the spinal cord.

### Purpose

Rhizotomy (also called dorsal rhizotomy, selective dorsal rhizotomy, and selective posterior rhizotomy) is a treatment for spasticity that is unresponsive to less invasive procedures.

### Demographics

Spasticity (involuntary muscle contractions) affects many thousands of Americans, but very few are affected seriously enough to require surgery for its treatment.

### Description

Rhizotomy is performed under **general anesthesia**. The patient lies face down. An incision is made along the lower spine, exposing the sensory nerve roots at the center the spinal cord. Individual nerve rootlets are electrically stimulated. Since these are sensory nerves, they should not stimulate muscle movement. Those that do (and therefore cause spasticity) are cut. Typically, one-quarter to one-half of nerve rootlets tested are cut.

### Diagnosis/Preparation

Rhizotomy is performed on patients with spasticity that is insufficiently responsive to oral medications or injectable therapies (botulinum toxin, phenol, or alcohol). It is most commonly performed for those patients with lower extremity spasticity that interferes with walking or severe spasticity that prevents hygiene or positioning of the legs. It is most commonly performed on children with cerebral palsy.

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

Rhizotomy is performed by a neurosurgeon in a hospital. The patient's neurologist and physical therapist may also be in attendance to help with the evaluation during surgery.

Patients undergoing rhizotomy receive a large battery of tests before the procedure, in order to document the functional effects of spasticity, and the patient's medical health and likely response to anesthesia and other operative stresses. Rhizotomy is performed as an in-patient procedure, and the patient is likely to require an overnight hospital stay before the operation.

### Aftercare

After surgery, the patient will spend one to several days in the hospital. Physical therapy and strength training usually begin the next day, in order to maximize the gains expected from surgery, and to keep the limbs mobile. Medication may be given for pain.

### Risks

Rhizotomy carries small but significant risks of nerve damage, permanent loss of sensation or altered sensation, weakness of the lower extremities, bowel and bladder dysfunction, increased likelihood of hip dislocation, and scoliosis progression. Anesthesia carries its own risks.

### Normal results

Rhizotomy reduces spasticity, which should allow more normal gait and improve mobility. Patients may require fewer walking aids, such as walkers or crutches.

### Morbidity and mortality rates

Other than the risks from anesthesia, rhizotomy does not carry a risk of **death** during surgery. Morbidity rates vary among centers performing the surgery. Persistent and significant adverse effects may occur in 1–5% of patients, including bowel or bladder changes and low back pain.

## QUESTIONS TO ASK THE DOCTOR

- How many rhizotomies have you performed?
- What is your complication rate?
- Is orthopedic surgery still likely to be necessary later on?

### Alternatives

Other spasticity treatments include oral medications and an implanted pump delivering baclofen to the space around the spinal cord (intrathecal baclofen). These may be appropriate alternatives for some patients. **Orthopedic surgery** can correct deformities that occur from untreated spasticity. Some controversy exists whether rhizotomy can delay or prevent the need for other spasticity procedures, especially orthopedic surgery such as **tenotomy**, with some evidence suggesting it can, and other evidence suggesting it may not.

## Robot-assisted surgery

### Definition

Robot-assisted surgery involves the use of a robot under the direction and guidance of a surgeon.

### Purpose

Robot-assisted surgery provides many benefits in the surgical care of patients. Computer-assisted robots provide exact motion and trajectories to minimize the side effects of surgical intervention. Robot-assisted surgeries can use three-dimensional imaging and smaller surgical tools to operate in a closed environment through smaller incisions. For example, traditional

methods of cardiac surgery usually required a six-to-eight inch incision in the sternum and the use of a heart-lung machine to maintain the functions of the heart and lungs while they are stopped for the surgery. Robot-assisted surgery has furthered the use of the keyhole approach, in which multiple small incisions are made between the ribs. With robot-assisted surgery, the surgeon is also able to make more precise movements using motion scaling. In this practice, an image is enlarged and the movements of the surgeon's hands are translated by the computer into smaller movements. This allows surgeons to perform more precisely, which can be especially important when the surgery is to be performed on particularly small parts of the body.

### Demographics

Patients undergoing surgical procedures classified as **neurosurgery**, **orthopedic surgery**, radio surgery and radiotherapy, prostatectomy, endoscopy, **laparoscopy**, cardiac surgery and craniofacial surgery may experience robot-assisted surgical techniques.

### Description

#### *Neurosurgery*

A high level of accuracy is required when operating on the brain to avoid damage to the sensitive brain tissue. Biopsies and minor interventions are best assisted by the robotic device. Interventions include drilling into the skull and making an incision through the dura mater to gain brain tissue samples, empty cysts, or eliminate hemorrhage.

#### *Orthopedic surgery*

Applications such as cementless hip-replacement, total knee arthroplasties, and pedicle screw placement can benefit from the more accurate cutting and drilling provided by a robot. Femur bone-cutting devices provide improved drilling to carve a cavity in the bone for prosthesis implant. Pins inserted into the bone before surgery are used as landmarks for computerized tomography (CT) imaging. The CT image provides the surgeon with the necessary information for choosing an implant. The surgeon removes the head from the femur bone, eliminating the joint. The leg is secured in position and the robot is brought into position. A high speed cutter is then applied to create the cavity, and then followed by a smoothing tool. The surgeon manually inserts the implant into the femur and completes the cap implant into the pelvic bone.

## KEY TERMS

**Arthoplastic**—Manufactured replacement joint.

**Cardiac surgery**—Surgery performed on the heart.

**Craniofacial surgery**—Surgery of the facial tissue and skull.

**Endoscopy**—Used to visualize internal structures of the body, such as the trachea, esophagus or intestines.

**Laparoscopy**—Surgery on internal structures through small incisions and visualized with the laparoscope.

**Neurosurgery**—Surgery performed on the brain.

**Orthopedic surgery**—Surgery performed on the bones. May include joint replacements and surgery of the vertebrae.

**Prostatectomy**—Performed for the treatment of prostate disease including prostate cancer.

**Radio surgery and radiotherapy**—Used in the treatment of cancerous growths or kidney stones.

### *Radiosurgery and radiotherapy*

Radiation treatment is provided by a robot. The CT image or magnetic resonance image (MRI) is used to determine where the radiation treatment should be delivered. The robot aligns with patient anatomy, delivering specific doses of radiation to the intended location.

### *Prostatectomy*

Removal of all or part of the prostate is another robot-assisted procedure. The robot controls instruments inserted through the urethra to the prostate gland. A diathermic hot wire cutting loop is guided to remove tissue in an appropriate pattern around the urethra. Fastening the guiding frame to the upper legs of the patient secures the device for accurate guidance.

### *Endoscopy*

Endoscopy is used to examine patient cavities for the presence of polyps, tumors, and other diseases. The endoscope can be better passed through cavities such as the colon or trachea. Three-dimensional images of the cavity are obtained and used to dictate the path taken by the endoscope. Sedation and heavy analgesia can be avoided.

## THE DA VINCI SURGICAL SYSTEM

Approved by the U.S. Food and Drug Administration in 2000, the da Vinci surgical system is the most popular surgical robotic system used in hospitals as of 2008. According to the company that manufactures the system, Intuitive Surgical, over 210 are used in hospitals throughout the world. The system has four robotic arms which move the cameras and tools the surgeon controls from a console. While the da Vinci costs over one million dollars, many surgeons who use the system say that it has become an indispensable aid to complicated surgical procedures. Moreover, it has been estimated that hospitals save money overall because the length of post-surgical hospitalization is cut in half.

### *Laparoscopy*

In laparoscopic surgeries, three to four small incisions are made in the abdominal or thoracic cavity to insert the instruments and video equipment. The surgeon performs the operation from a remote console that provides the human-machine interface. The console provides video monitoring images that are three-dimensional. Joysticks are used to manipulate the tools within the chest cavity to complete the surgical procedure.

### *Cardiac surgery*

Robots can be used in the coronary artery bypass grafting surgeries and cardiac valve replacement and repair surgeries. The harvesting of artery and vein grafts can also be accomplished with the aid of laparoscopic techniques.

### *Craniofacial surgery*

Difficult bone cuts and bone tumor removals are accomplished successfully using robotic instruments. Pre-planned trajectories are programmed into the machine. Precision cuts are made in the manner desired to achieve an aesthetically satisfactory result. As the surgeon manipulates the saw, he or she is guided along the path by a predetermined trajectory determined during an initial run on a model of the surgical site.

### *Aftercare*

The patient should expect a faster recovery than that achieved by traditional surgery procedures.

## QUESTIONS TO ASK THE DOCTOR

- Is there an institution in the vicinity which uses robot-assisted surgery?
- How experienced is the surgeon with robot-assisted surgical techniques?
- What benefits would the robot-assisted surgery provide?
- What complications can be avoided and which may be encountered with robot-assisted surgery?

### Risks

With some of these procedures, a longer surgical time is required to achieve the same desired outcome as the traditional surgical approach. There is an increased risk of anesthesia related complications as surgical times increase. Additionally, if the robotic procedure is not completed successfully, the surgeon may need to complete the procedure with a traditional technique.

### Normal results

Results for each procedure are comparable to or better than the standard surgical procedure.

### Morbidity and mortality rates

Complications should be comparable to the standard surgical procedure, and even reduced. Some complications may only be associated with the robot-assisted procedure.

### Alternatives

The alternative to using robot-assisted surgery is for the surgeon to employ a traditional surgical approach.

## Root canal treatment

### Definition

Root canal treatment, also known as endodontic treatment, is a dental procedure in which the diseased or damaged pulp (central core) of a tooth is removed and the inside areas (the pulp chamber and root canals) are filled and sealed.

### Purpose

An inflamed or infected pulp is called pulpitis. It is the most common cause of a toothache. To relieve the pain and prevent further complications, the tooth may be extracted (surgically removed) or saved by root canal treatment.

### Demographics

Root canal treatment has become a common dental procedure. According to the American Association of Endodontists, more than 14 million root canal treatments are performed every year, with a 95% success rate.

### Description

Inside the tooth, the pulp of a tooth is comprised of soft tissue that contains the blood supply, by which the tooth receives its nutrients; and the nerve, by which the tooth senses hot and cold. This tissue is vulnerable to damage from deep dental decay, accidental injury, tooth fracture, or trauma from repeated dental procedures such as multiple fillings or restorations over time. If a tooth becomes diseased or injured, bacteria may build up inside the pulp, spreading infection from the natural crown of the tooth to the root tips in the jawbone. Pus accumulating at the ends of the roots can form a painful abscess that can damage the bone supporting the teeth. Such an infection may produce pain that is severe, constant, or throbbing. It can also

During a root canal, the diseased pulp of a tooth (A), is removed (B). The remaining empty tooth is filled and sealed with a filling or crown. (Illustration by GGS Information Services. Cengage Learning, Gale.)

## KEY TERMS

**Abscess**—A cavity or space in tooth or gum tissue filled with pus as the result of infection. Its swelling exerts pressure on the surrounding tissues, causing pain.

**Apicoectomy**—Also called root resectioning. The root tip of a tooth is accessed in the bone and a small amount is shaved away. The diseased tissue is removed and a filling is placed to reseal the canal.

**Crown**—The natural crown of a tooth is that part of the tooth covered by enamel. Also, a restorative crown is a protective shell that fits over a tooth.

**Endodontic**—Pertaining to the inside structures of the tooth, including the dental pulp and tooth root, and the periapical tissue surrounding the root.

**Endodontist**—A dentist who specializes in the diagnosis and treatment of disorders affecting the inside structures of teeth.

**Extraction**—The surgical removal of a tooth from its socket in a bone.

**Gutta percha**—An inert, latex-like substance used for filling root canals.

**Pulp**—The soft innermost layer of a tooth, containing blood vessels and nerves.

**Pulp chamber**—The area within the tooth occupied by dental pulp.

**Pulpitis**—Inflammation of the pulp of a tooth involving the blood vessels and nerves.

**Root canal**—The space within a tooth that runs from the pulp chamber to the tip of the root.

**Root canal treatment**—The process of removing diseased or damaged pulp from a tooth, then filling and sealing the pulp chamber and root canals.

result in prolonged sensitivity to heat or cold, swelling, and tenderness in the surrounding gums, facial swelling, or discoloration of the tooth. In some cases, however, the pulp may die so gradually that there is little noticeable pain.

Root canal treatment is performed under **local anesthesia**. A thin sheet of rubber, called a rubber dam, is placed in the mouth and around the base of the tooth to isolate the tooth and help to keep the operative field dry. The dentist removes any tooth decay and makes an opening through the natural crown of the tooth into the pulp chamber. Creating

this access also relieves the pressure inside the tooth and can dramatically ease pain.

The dentist determines the length of the root canals, usually with a series of x rays. Small wire-like files are then used to clean the entire canal space of diseased pulp tissue and bacteria. The debris is flushed out with large amounts of water (irrigation). The canals are also slightly enlarged and shaped to receive an inert (non-reactive) filling material called gutta percha. However, the tooth is not filled and permanently sealed until it is completely free of active infection. The dentist may place a temporary seal, or leave the tooth open to drain, and prescribe an antibiotic to counter any spread of infection from the tooth. This is why root canal treatment may require several visits to the dentist.

Once the canals are completely clean, they are filled with gutta percha and a sealer cement to prevent bacteria from entering the tooth in the future. A metal post may be placed in the pulp chamber for added structural support and better retention of the crown restoration. The tooth is protected by a temporary filling or crown until a permanent restoration may be made. This restoration is usually a gold or porcelain crown, although it may be a gold inlay, or an amalgam or composite filling (paste fillings that harden).

### Diagnosis/Preparation

Signs that a root canal treatment is necessary include severe pain while chewing, prolonged sensitivity to heat or cold, or a darkening of the tooth. Swelling and tenderness of the gums or pimples appearing on the gums are also common symptoms. However, it is also possible that no symptoms will be noticed. The dentist will take an x ray of the tooth to determine if there is any sign of infection in the surrounding bone.

### Aftercare

Once a root canal treatment is performed, the recipient must have a crown placed over the tooth to protect it. The cost of the treatment and the crown may be expensive. However, replacing an extracted tooth with a fixed bridge, a removable partial denture, or an implant to maintain the space and restore the chewing function is typically even more expensive.

During the time when **antibiotics** are being used, care should be taken to avoid using the tooth to chew food. The tooth has been structurally weakened and may break, or there is a possibility of the interior of the tooth becoming reinfected.

If the tooth feels sensitive following the procedure, a standard over-the-counter pain medication such as

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

A root canal treatment may be performed by a general dentist or by an endodontist. An endodontist is a dentist who specializes in endodontic (literally “inside of the tooth”) procedures. The procedure is usually performed in a professional dental office. In rare situations, it may be performed in a hospital outpatient facility.

ibuprofen or naproxen may be taken. This sensitivity will fade after a few days. In most cases the patient can resume regular activity the following day.

### Risks

There is a possibility that a root canal treatment will not be successful the first time. If infection and inflammation recur and an x ray indicates a repeat treatment is feasible, the old filling material is removed and the canals are thoroughly cleaned out. The dentist will try to identify and correct problems with the first root canal treatment before filling and sealing the tooth a second time.

In cases where an x ray indicates that another root canal treatment cannot correct the problem, endodontic surgery may be performed. In a procedure called an apicoectomy, or root resectioning, the root end of the tooth is accessed in the bone, and a small amount is shaved away. The area is cleaned of diseased tissue and a filling is placed to reseal the canal.

### Normal results

With successful root canal treatment, the tooth will no longer cause pain. However, because it does not contain an internal nerve, it no longer has sensitivity to hot, cold, or sweets. Because these are signs of dental decay, the root canal recipient must receive regular dental check-ups with periodic x rays to avoid further disease in the tooth. The restored tooth may last a lifetime. However, with routine wear, the filling or crown may eventually need to be replaced.

### Morbidity and mortality rates

In some cases, despite proper root canal treatment and endodontic surgery, the tooth dies and must be extracted. This is relatively uncommon.

## QUESTIONS TO ASK THE DOCTOR

What will be the resulting functional capacity of the tooth?

Is the oral surgeon board certified in endodontic surgery?

How many root canal procedures has the oral surgeon performed?

What is the oral surgeon's complication rate?

### Alternatives

The only alternative to performing a root canal procedure is to extract the diseased tooth. After restoration or extraction, the two main goals are to allow normal chewing and to maintain proper alignment and spacing between teeth. A fixed bridge, a removable partial denture or an implant will accomplish both goals. However, these are usually more expensive than a root canal treatment.

## Rotator cuff repair

### Definition

Rotator cuff surgery is the repair of inflammation or tears of the rotator cuff tendons in the shoulder. There are four tendons in the rotator cuff, and these tendons are attached individually to the following muscles: teres minor, subscapularis, infraspinatus, and the supraspinatus. The tears and inflammation associated with rotator cuff injury occur in the region near where these tendon/muscle complexes attach to the humerus (upper arm) bone.

### Purpose

Rotator cuff surgery is necessary when chronic shoulder pain associated with rotator cuff injury does not respond to conservative therapy such as rest, heat/ice application, or the use of non-steroidal anti-inflammatory drugs (NSAIDs). Rotator cuff injuries are often lumped into the category referred to as rotator cuff syndrome. Rotator cuff syndrome describes a range of symptoms from basic sprains and tendon swelling (tendonitis) to total rupture or tearing of the tendon.

### Demographics

Approximately 5–10% of the general population is believed to have rotator cuff syndrome at a given time. It is not commonly found in individuals under the age of 20 years, even though many in this population are athletically active. In general, males are more likely than females to develop rotator cuff syndrome and require surgery. Most rotator cuff injuries are

A rotator cuff injury results in a torn tendon at the top of the shoulder (A). To repair it, an incision is made over the site of the tear (B). The tendon's attachment to the bone is repaired with sutures (C), and a small piece of bone from the acromion may be removed (D) to ensure smoother movement of the tendons. (Illustration by GGS Information Services. Cengage Learning, Gale.)

associated with athletic activities such as baseball, tennis, weight lifting, and swimming, where the arms are repeatedly lifted over the head. Rotator cuff injuries can also occur in accidents involving falling to the ground or when the humerus is pushed into the shoulder socket. Rotator cuff injuries can also occur in older, active individuals because the rotator cuff tendons begin to deteriorate after age 40. Occupations that have been associated with rotator cuff injuries

include nursing, painting, carpentry, tree pruning, fruit picking, and grocery clerking.

### Description

For most patients, if the pain begins to subside, they are encouraged to undergo a period of physical therapy. If the pain does not subside after a few weeks, then the physician may suggest the use of cortisone

## KEY TERMS

**Adhesions**—A fibrous band that holds together tissue that are usually separated and that are associated with wound healing.

**Arthrography**—Visualization of a joint by radiographic means following injection of a contrast dye into the joint space.

**Arthroscope**—An endoscope, or a tube containing an optical system, that is used to examine the interior of a joint.

**Bone spurs**—A sharp or pointed calcified projection.

**Bursa**—A sac found in connective tissue that acts to reduce friction between tendon and bone.

**Deltoid muscle**—Muscle that covers the prominence of the shoulder.

injections into the shoulder region. Rotator cuff repair is then considered if the more conservative methods are not successful.

The primary aim of rotator cuff repair is to repair the connection between the damaged tendon and the bone. Once this bridge is re-established and the connection between the tendon and the bone has thoroughly healed, the corresponding muscles can once again move the arm in a normal fashion. The goal of the surgery is to ensure the smooth movement of the rotator cuff tendons and bursa under the upper part of the shoulder blade. The surgery is also performed to improve the comfort of the patient and to normalize the function of the shoulder and arm. There are a variety of surgical approaches that can be used to accomplish rotator cuff repair. The most common approach is called the anterior acromioplasty approach. This approach allows for excellent access to the most common sites of tears—the biceps groove, anterior cuff, and the undersurface of the joint.

Three types of rotator cuff repair surgeries are performed: open incision, mini-open incision, and arthroscopic. Most rotator cuff repairs are accomplished using incisions that minimize cosmetic changes in the skin following healing. If possible, the surgery is performed with an arthroscope to minimize cosmetic damage to the skin. Typically, the incision made is about the size of a buttonhole. The arthroscope, a pencil-sized instrument, is then inserted into the joint. The surgeon usually accesses the rotator cuff by opening part of the deltoid muscle. If bone spurs, adhesions, and damaged bursa are present in the

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

Rotator cuff repair is generally performed by a specialist known as an orthopedic surgeon, who has received specialized training in the diseases and injuries of the musculoskeletal system. Orthopedic surgeons who perform rotator cuff repair receive extensive training in general surgery and in the specific techniques involving the musculoskeletal system. Rotator cuff repairs are often performed in the specialized department of a general hospital, but they are also performed in specialized orthopedic surgery clinics or institutes for orthopedic conditions.

rotator cuff region, then the surgeon will generally remove these damaged structures to improve function in the joint. In cases where the arthroscopic technique is not advised or when it fails to achieve the desired results, a conversion to open surgery is made. This involves a larger incision and usually requires more extensive anesthesia and a longer recovery period.

The success of the rotator cuff repair is dependent on the following factors:

- age of the patient
- type of surgical technique employed
- degree of damage present
- patient's recovery goals
- patient's ability to follow a physical therapy program following surgery
- smoking status
- number of previous cortisone injections

## Diagnosis/Preparation

The diagnosis of rotator cuff injury is based on a combination of clinical signs and symptoms, coupled with diagnostic testing. The most common clinical signs and symptoms include:

- tenderness in the rotator cuff
- pain associated with the movement of the arm above the head
- pain that is fairly constant but more intense at night
- weakness or pain with the forward movement of the arm
- muscle atrophy (wasting) in long-term injuries that involve a complete tendon tear

## QUESTIONS TO ASK THE DOCTOR

- What are my alternatives?
- Is surgery the answer for me?
- Can you recommend a surgeon who performs rotator cuff repairs?
- If surgery is appropriate for me, what are the next steps?

X rays are used to rule out other types of injuries or abnormalities present in the shoulder region. While x rays are often used to help solidify the diagnosis, **arthrography**, ultrasonography, computed tomography (CT), and **magnetic resonance imaging** (MRI) are the definitive tests in the diagnosis of rotator cuff injury. Arthrography and ultrasonography of the shoulder can help determine whether or not there is a full tear in the rotator cuff. A MRI can help determine whether there is a full tear, partial tear, chronic tendonitis, or other cause of the shoulder pain. The final decision to repair the tear ultimately rests on the amount of pain and restriction suffered by the patient.

### Aftercare

Following the procedure, the patient will typically spend several hours in the **recovery room**. Generally, an ice pack will be applied to the affected shoulder joint for a period up to 48 hours. The patient will usually be given either prescription or non-prescription pain medication. The dressing is usually removed the day after surgery and is replaced by adhesive strips. The patient should contact a physician if there are any significant changes in the affected area once the patient goes home. These changes can include increased swelling, pain, bleeding, drainage in the affected area, nausea, vomiting, or signs of infection. Signs of infection include fever, dizziness, headache, and muscle aches.

It often takes several days for the arthroscopic puncture wounds to heal, and the joint usually takes several weeks to recover. Most patients can resume normal daily activities, with the permission of a physician, within a few days following the procedure. Most patients are advised to undergo a rehabilitation program that includes physical therapy. Such a program can facilitate recovery and improve the functioning of the joint in the future.

## QUESTIONS TO ASK THE SURGEON

- How many times have you performed rotator cuff repair?
- Are you a board-certified surgeon?
- What type of outcomes have you had?
- What are the most common side effects or complications?
- What should I do to prepare for surgery?
- What should I expect following the surgery?
- Can you refer me to one of your patients who has had this procedure?
- What type of diagnostic procedures are performed to determine if patients require surgery?
- Will I need to see another specialist for the diagnostic procedures?

### Risks

Complications following arthroscopic rotator cuff surgery are very rare. Such complications occur in less than 1% of cases. These complications include instrument breakage, blood vessel or nerve damage, blood vessel clots, infection, and inflammation. Complications, though still rare, are more common following open surgery. This is due to the larger incisions and more complicated anesthesia that is often necessary.

### Normal results

The prognosis for the long-term relief from rotator cuff syndrome is good, especially when both conservative and surgical therapeutic approaches are used. In those patients who do require surgery, six weeks of physical therapy is typically instituted following surgery. Complete recovery following surgery may take several months. In rare cases, the rotator cuff injury is so severe that the patient may require muscle transfers and tendon grafts. Even more rarely, the injury can be so severe that the tendons are not repairable. This typically occurs when a severe rotator cuff injury is neglected for a long period of time.

### Morbidity and mortality rates

Morbidity is rare in both the arthroscopic and open procedures. Mortality is exceedingly rare in patients undergoing rotator cuff repair.

## Alternatives

Conservative approaches are typically used before surgery is considered in patients with rotator cuff injury. This is true even in cases where there is evidence of a full tendon tear. Some patients with a full or partial tear do not suffer a significant amount of pain and retain normal or nearly normal range of motion in shoulder movement. A majority of those with rotator cuff syndrome respond to conservative non-surgical approaches. Conservative therapies include the following:

- heat or ice to reduce pain and swelling
- cessation or reduction of activities that involve the movement of the arms overhead
- medication such as non-steroidal anti-inflammatory agents to reduce pain and inflammation
- cortisone injections to reduce pain and inflammation
- rest

Once the pain begins to subside, the patient usually is encouraged to begin a program of physical therapy to help re-institute normal motion and function to the shoulder.

## Sacral nerve stimulation

### Definition

Sacral nerve stimulation, also known as sacral neuromodulation, is a procedure in which the sacral nerve at the base of the spine is stimulated by a mild electrical current from an implanted device. It is done to improve functioning of the urinary tract, to relieve pain related to urination, and to control fecal incontinence.

### Purpose

As a proven treatment for urinary incontinence, sacral nerve stimulation (SNS) has recently been found effective in the treatment of interstitial cystitis, a disorder that involves hyperreflexia of the urinary sphincter. SNS is also used to treat pelvic or urinary pain as well as fecal incontinence.

A person's ability to hold urine or feces depends on three body functions:

- a reservoir function represented by the urethra/bladder or colon
- a gatekeeping function represented by the urethral or anal sphincter and
- the brain's ability to control urination, defecation, and nerve sensitivity

A dysfunction or deficiency in any of these components can result in incontinence. The most common forms of incontinence are stress urinary incontinence and urge incontinence. Stress incontinence is related to an unstable detrusor muscle that controls the urinary sphincter. When the detrusor muscle is weak, urine can leak out of the bladder from pressure on the abdomen caused by sneezing, coughing, and other movements. Urge incontinence is characterized by a sudden strong need to urinate and inability to hold urine until an appropriate time; it is also associated with hyperactivity of the urinary sphincter. Both conditions can be treated by SNS. SNS requires an implanted device

that sends continuous stimulation to the sacral nerve that controls the urinary sphincter. This treatment has been used with over 1500 patients with a high rate of success. It was approved in Europe in 1994. The Food and Drug Administration (FDA) approved SNS for the treatment of urinary urge incontinence in 1997 and for urinary frequency in 1999.

Interstitial cystitis (IC) is a chronic condition of unknown origin that causes pain in the bladder and lower abdomen, urinary urgency, a frequent need to urinate at night, and pain during intercourse. IC has no known cause; it is diagnosed by the level of reported discomfort and by excluding other sources of urinary pain, frequency and urgency. SNS has only recently been used to treat IC. According to three studies presented to the American Urological Association in 2001, SNS significantly reduced urinary urgency and frequency, with some relief of pain, in patients who had not responded to other treatments. The use of SNS in treating IC is still considered experimental, however.

Treatment of fecal incontinence with SNS is very recent; it is also considered experimental. Newer research from Italy, however, indicates that patients with anorectal disturbances that are usually treated by augmentation of the sphincter muscle or implanting an artificial sphincter can benefit from electrical stimulation of the sacral nerve. Although the mechanism of SNS is not completely clear, researchers believe that the patient's control of the pelvic region is restored by the stimulation or activation of afferent fibers in the muscles of the pelvic floor.

### Demographics

Urinary incontinence affects between 15% and 30% of American adults living in the community, and as many as 50% of people confined to **nursing homes**. It is a disorder that affects women far more frequently than men; 85% of people suffering from urinary incontinence are women. According to the chief of geriatrics

## KEY TERMS

**Afferent fibers**—Nerve fibers that conduct nerve impulses from tissues and organs toward the central nervous system.

**Detrusor muscle**—The medical name for the layer of muscle tissue covering the urinary bladder. When the detrusor muscle contracts, the bladder expels urine.

**Fecal incontinence**—Inability to control bowel movements.

**Hyperreflexia**—A condition in which the detrusor muscle of the bladder contracts too frequently, leading to inability to hold one's urine.

**Interstitial cystitis**—A condition of unknown origin that causes urinary urgency, pain in the bladder and abdomen, and pain during sexual intercourse.

**Neuromodulation**—Electrical stimulation of a nerve for relief of pain.

**Sacral nerve**—The nerve in the lower back region of the spine that controls the need to urinate.

**Sphincter**—A ringlike band of muscle that tightens or closes the opening to a body organ.

**Urgency**—A sudden compelling need to urinate.

**Urinary incontinence**—Inability to control urination.

at a Boston hospital, 25 million Americans suffer each year from occasional episodes of urinary or fecal incontinence.

Interstitial cystitis is less common than urinary or fecal incontinence but still affects about 12% of women in the United States each year. The average age of IC patients is 40; 25% of patients are younger than 30. Although 90% of patients diagnosed with IC are women, it is thought that the disorder may be underdiagnosed in men.

## Description

Sacral nerve stimulation (SNS) is conducted through an implanted device that includes a thin insulated wire called a lead and a neurostimulator much like a cardiac pacemaker. The device is inserted in a pocket in the patient's lower abdomen. SNS is first tried on an outpatient basis in the doctor's office with the implantation of a test lead. If the trial treatment is successful, the patient is scheduled for inpatient surgery.

Permanent surgical implantation is done under **general anesthesia** and requires a one-night stay in the hospital. After the patient has been anesthetized, the surgeon implants the neurostimulator, which is about the size of a pocket stopwatch, under the skin of the patient's abdomen. Thin wires, or leads, running from the stimulator carry electrical pulses from the stimulator to the sacral nerves located in the lower back. After the stimulator and leads have been implanted, the surgeon closes the incision in the abdomen.

## Diagnosis/Preparation

Incontinence significantly affects a patient's quality of life; thus patients usually consult a doctor when their urinary problems begin to cause difficulties in the workplace or on social occasions. A family care practitioner will usually refer the patient to a urologist for diagnosis of the cause(s) of the incontinence. Patients with urinary and fecal incontinence are evaluated carefully through the taking of a complete patient history and a **physical examination**. The doctor will use special techniques to assess the capacity of the bladder or rectum as well as the functioning of the urethral or anal sphincter in order to determine the cause or location of the incontinence. **Cystoscopy**, which is the examination of the full bladder with a scope attached to a small tube, allows the physician to rule out certain disorders as well as plan the most effective treatment. These extensive tests are especially important in diagnosing interstitial cystitis because all other causes of urinary urgency, frequency, and pain must be ruled out before surgery can be suggested. Cystoscopy is done under anesthesia and often works as a treatment for IC. Once the doctor has made the diagnosis of urinary incontinence due to sphincter insufficiency, he or she will explain and discuss the surgical implant with the patient. SNS may be tried out on a temporary basis. The same pattern of diagnosis and treatment is used for patients with IC and fecal incontinence. Temporary implants can help eliminate those patients who will not benefit from a permanent implant.

## Aftercare

Following surgery, the patient remains overnight in the hospital. **Antibiotics** may be given to reduce the risk of infection and pain medications to relieve discomfort. The patient will be given instructions on **incision care** and follow-up appointments before he or she leaves the hospital.

Aftercare includes fine-tuning of the SNS stimulator. The doctor can adjust the strength of the electrical

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

SNS devices are implanted under general anesthesia by urologists, who are physicians specializing in treating disorders of the urinary tract. The procedure is usually performed in a hospital.

impulses in his or her office with a handheld programmer. The stimulator runs for about five to 10 years and can be replaced during an outpatient procedure. About a third of patients require a second operation to adjust or replace various elements of the stimulator device.

### Risks

In addition to the risks of bleeding and infection that are common to surgical procedures, implanting an SNS device carries the risks of pain at the insertion site, discomfort when urinating, mild electrical shocks, and displacement or dislocation of the leads.

### Normal results

Patients report improvement in the number of urinations, the volume of urine produced, lessened urgency, and higher overall quality of life after treatment with SNS. Twenty-two patients undergoing a three- to seven-day test of sacral nerve stimulation on an outpatient basis reported significant reduction in urgency and frequency, according to the American Urological Association. Studies have indicated complete success in about 50% of patients. Sacral nerve stimulation is being used to treat fecal incontinence in the United States and Europe, with promising early reports. As of 2003, SNS is the least invasive of the recognized surgical treatments for fecal incontinence.

### Morbidity and mortality rates

Sacral nerve stimulation has been shown to be a safe and effective procedure for the treatment of both urinary and fecal incontinence. Two groups of researchers, in Spain and the United Kingdom respectively, have reported that “The effects of neuromodulation are long-lasting and associated morbidity is low.” The most commonly reported complications of SNS are pain at the site of the implant (15.3% of patients); pain on urination (9%); and displacement of the leads (8.4%).

## QUESTIONS TO ASK THE DOCTOR

- Am I likely to benefit from SNS?
- How many stimulators have you implanted?
- How many of your patients consider SNS a successful treatment?
- What side effects have your patients reported?

### Alternatives

There are three types of nonsurgical treatments that benefit some patients with IC:

- Behavioral approaches. These include biofeedback, diet modifications, bladder retraining, and pelvic muscle exercises.
- Medications. These include antispasmodic drugs, tricyclic antidepressants, and pentosan polysulfate sodium, which is sold under the trade name Elmiron. Elmiron appears to work by protecting the lining of the bladder from bacteria and other irritating substances in urine.
- Intravesical medications. These are medications that affect the muscular tissues of the bladder. Oxybutynin is a drug that is prescribed for patients who are incontinent because their bladders fail to store urine properly. Capsaicin and resiniferatoxin are used to treat hyperreflexia of the detrusor muscle.

Surgical alternatives to SNS are considered treatments of last resort for IC because they are invasive, irreversible, and benefit only 30–40% of patients. In addition, some studies indicate that these surgeries can lead to long-term kidney damage. They include the following procedures:

- Augmentation cystoplasty. In this procedure, the surgeon removes the patient’s bladder and replaces it with a section of the bowel—in effect creating a new bladder. The patient passes urine through the urethra in the normal fashion.
- Urinary diversion. The surgeon creates a tube from a section of the patient’s bowel and places the ureters (tubes that carry urine from the kidneys to the bladder) in this tube. The tube is then attached to a stoma, or opening in the abdomen. Urine is carried into an external collection bag that the patient must empty several times daily.
- Internal pouch. The surgeon creates a new bladder from a section of the bowel and attaches it inside the abdomen. The patient empties the pouch by self-catheterization four to six times daily.

## Salpingo-oophorectomy

### Definition

Unilateral salpingo-oophorectomy is the surgical removal of a fallopian tube and an ovary. If both sets of fallopian tubes and ovaries are removed, the procedure is called a bilateral salpingo-oophorectomy.

### Purpose

This surgery is performed to treat ovarian or other gynecological cancers, or infections caused by pelvic inflammatory disease. Occasionally, removal of one or both ovaries may be done to treat endometriosis, a

condition in which the lining of the uterus (the endometrium) grows outside of the uterus (usually on and around the pelvic organs). The procedure may also be performed if a woman has been diagnosed with an ectopic pregnancy in a fallopian tube and a **salpingostomy** (an incision into the fallopian tube to remove the pregnancy) cannot be done. If only one fallopian tube and ovary are removed, the woman may still be able to conceive and carry a pregnancy to term. If both are removed, however, the woman is rendered permanently infertile. This procedure is commonly combined with a **hysterectomy** (surgical removal of the uterus); the ovaries and fallopian tubes are removed in about one-third of hysterectomies.

Until the 1980s, women over age 40 having hysterectomies routinely had healthy ovaries and fallopian tubes removed at the same time. Many physicians reasoned that a woman over 40 was approaching menopause and soon her ovaries would stop secreting estrogen and releasing eggs. Removing the ovaries would eliminate the risk of ovarian cancer and only accelerate menopause by a few years.

In the 1990s, the thinking about routine salpingo-oophorectomy began to change. The risk of ovarian cancer in women who have no family history of the disease is less than 1%. Moreover, removing the ovaries increases the risk of cardiovascular disease and accelerates osteoporosis unless a woman takes prescribed hormone replacements.

### Demographics

Overall, ovarian cancer accounts for only 4% of all cancers in women. For women at increased risk, **oophorectomy** may be considered after the age of 35 if childbearing is complete. Factors that increase a woman's risk of developing ovarian cancer include age (most ovarian cancers occur after menopause), the presence of a mutation in the BRCA1 or BRCA2 gene, the number of menstrual periods a woman has had (affected by age of onset, pregnancy, breastfeeding, and oral contraceptive use), history of breast cancer, diet, and family history. The incidence of ovarian cancer is highest among Native American (17.5 cases per 100,000 population), Caucasian (15.8 per 100,000), Vietnamese (13.8 per 100,000), Hispanic (12.1 per 100,000), and Hawaiian (11.8 per 100,000) women; it is lowest among Korean (7.0 per 100,000) and Chinese (9.3 per 100,000) women. African American women have an ovarian cancer incidence of 10.2 per 100,000 population.

Endometriosis, another reason why salpingo-oophorectomy may be performed, has been estimated

## Salpingo-oophorectomy

In a salpingo-oophorectomy, a woman's reproductive organs are accessed through an incision in the lower abdomen, or laparoscopically (A). Once the area is visualized, a diseased fallopian tube can be severed from the uterus and removed (B and C). The ovary can also be removed with the tube (D). The remaining structures are stitched (E), and the wound is closed. (Illustration by GGS Information Services. Cengage Learning, Gale.)

## KEY TERMS

**BRCA1 or BRCA2 genetic mutation**—A genetic mutation that predisposes otherwise healthy women to breast cancer.

**Endometriosis**—A painful disease in which cells from the lining of the uterus (endometrium) become attached to other organs in the pelvic cavity. The condition is hard to diagnose and often causes severe pain as well as infertility.

**Fallopian tubes**—Tubes that extend from either end of the uterus that convey the egg from the ovary to the uterus during each monthly cycle.

**Hysterectomy**—The surgical removal of the uterus.

**Ureter**—The tube that carries urine from the bladder to the kidneys.

to affect up to 10% of women. Approximately four out of every 1,000 women are hospitalized as a result of endometriosis each year. Women 25–35 years of age are affected most, with 27 being the average age of diagnosis.

## Description

General or regional anesthesia will be given to the patient before the procedure begins. If the procedure is performed through a laparoscope, the surgeon can avoid a large abdominal incision and can shorten recovery. With this technique, the surgeon makes a small cut through the abdominal wall just below the navel. A tube containing a tiny lens and light source (a laparoscope) is then inserted through the incision. A camera can be attached that allows the surgeon to see the abdominal cavity on a video monitor. When the ovaries and fallopian tubes are detached, they are removed through a small incision at the top of the vagina. The organs can also be cut into smaller sections and removed. When the laparoscope is used, the patient can be given either regional or **general anesthesia**; if there are no complications, the patient can leave the hospital in a day or two.

If a laparoscope is not used, the surgery involves an incision 4–6 in (10–15 cm) long into the abdomen extending either vertically up from the pubic bone toward the navel, or horizontally (the “bikini incision”) across the pubic hairline. The scar from a bikini incision is less noticeable, but some surgeons prefer the vertical incision because it provides greater visibility while operating. A disadvantage to abdominal salpingo-oophorectomy is that bleeding is more likely

to be a complication of this type of operation. The procedure is more painful than a laparoscopic operation and the recovery period is longer. A woman can expect to be in the hospital two to five days and will need three to six weeks to return to normal activities.

## Diagnosis/Preparation

Before surgery, the doctor will order blood and urine tests, and any additional tests such as **ultrasound** or x rays to help the surgeon visualize the woman’s condition. The woman may also meet with the anesthesiologist to evaluate any special conditions that might affect the administration of anesthesia. A colon preparation may be done, if extensive surgery is anticipated.

On the evening before the operation, the woman should eat a light dinner, then take nothing by mouth, including water or other liquids, after midnight.

## Aftercare

If performed through an abdominal incision, salpingo-oophorectomy is major surgery that requires three to six weeks for full recovery. However, if performed laparoscopically, the recovery time can be much shorter. There may be some discomfort around the incision for the first few days after surgery, but most women are walking around by the third day. Within a month or so, patients can gradually resume normal activities such as driving, exercising, and working.

Immediately following the operation, the patient should avoid sharply flexing the thighs or the knees. Persistent back pain or bloody or scanty urine indicates that a ureter may have been injured during surgery.

If both ovaries are removed in a premenopausal woman as part of the operation, the sudden loss of estrogen will trigger an abrupt premature menopause that may involve severe symptoms of hot flashes, vaginal dryness, painful intercourse, and loss of sex drive. (This is also called “surgical menopause.”) In addition to these symptoms, women who lose both ovaries also lose the protection these hormones provide against heart disease and osteoporosis many years earlier than if they had experienced natural menopause. Women who have had their ovaries removed are seven times more likely to develop coronary heart disease and much more likely to develop bone problems at an early age than are premenopausal women whose ovaries are intact. For these reasons, some form of hormone replacement therapy (HRT) may be prescribed to relieve the symptoms of surgical menopause and to help prevent heart and bone disease.

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

Salpingo-oophorectomies are usually performed in a hospital operating room by a gynecologist, a medical doctor who has completed specialized training in the areas of women's general health, pregnancy, labor and childbirth, prenatal testing, and genetics.

Reaction to the removal of fallopian tubes and ovaries depends on a wide variety of factors, including the woman's age, the condition that required the surgery, her reproductive history, how much social support she has, and any previous history of depression. Women who have had many gynecological surgeries or chronic pelvic pain seem to have a higher tendency to develop psychological problems after the surgery.

### Risks

Major surgery always involves some risk, including infection, reactions to the anesthesia, hemorrhage, and scars at the incision site. Almost all pelvic surgery causes some internal scars, which in some cases can cause discomfort years after surgery.

Potential complications after a salpingo-oophorectomy include changes in sex drive, hot flashes, and other symptoms of menopause if both ovaries are removed. Women who have both ovaries removed and who do not take estrogen replacement therapy run an increased risk for cardiovascular disease and osteoporosis. Women with a history of psychological and emotional problems before an oophorectomy are more likely to experience psychological difficulties after the operation.

### Normal results

If the surgery is successful, the fallopian tubes and ovaries will be removed without complication, and the underlying problem resolved. In the case of cancer, all the cancer will be removed. A woman will become infertile following a bilateral salpingo-oophorectomy.

### Morbidity and mortality rates

Studies have shown that the complication rate following salpingo-oophorectomy is essentially the same as

## QUESTIONS TO ASK THE DOCTOR

- Why is a salpingo-oophorectomy being recommended?
- How will the procedure be performed?
- Will one or both sets of ovaries/fallopian tubes be removed?
- What alternatives to salpingo-oophorectomy are available to me?

that following hysterectomy. The rate of complications differs by the type of hysterectomy performed. Abdominal hysterectomy is associated with a higher rate of complications (9.3%), while the overall complication rate for vaginal hysterectomy is 5.3%, and 3.6% for laparoscopic vaginal hysterectomy. The risk of **death** is about one in every 1,000 (1/1,000) women having a hysterectomy. The rates of some of the more commonly reported complications are:

- excessive bleeding (hemorrhaging): 1.8–3.4%
- fever or infection: 0.8–4.0%
- accidental injury to another organ or structure: 1.5–1.8%

Because of the cessation of hormone production that occurs with a bilateral oophorectomy, women who lose both ovaries also prematurely lose the protection these hormones provide against heart disease and osteoporosis. Women who have undergone bilateral oophorectomy are seven times more likely to develop coronary heart disease and much more likely to develop bone problems at an early age than are premenopausal women whose ovaries are intact.

### Alternatives

Depending on the specific condition that warrants an oophorectomy, it may be possible to modify the surgery so at least a portion of one ovary remains, allowing the woman to avoid early menopause. In the case of endometriosis, there are a number of alternative treatments that are usually pursued before a salpingo-oophorectomy (with or without hysterectomy) is performed. These include excising the growths without removing any organs, blocking or destroying the nerves that provide sensation to some of the pelvic structures, or prescribing drugs that decrease estrogen levels.

## Salpingostomy

### Definition

A salpingostomy is a surgical incision into a fallopian tube. This procedure may be done to repair a damaged tube or to remove an ectopic pregnancy (one that occurs outside of the uterus).

### Purpose

The fallopian tubes are the structures that carry a mature egg from the ovaries to the uterus. These tubes, which are about 4 inches (10 cm) long and 0.2 inches (0.5 cm) in diameter, are found on the upper outer sides of the uterus, and open into the uterus through

small channels. It is within the fallopian tubes that fertilization, the joining of an egg and a sperm, takes place.

During a normal pregnancy, the fertilized egg passes from the fallopian tubes into the uterus and then implants into the lining of the uterus. If the fertilized egg implants anywhere outside of the uterus, it is called an ectopic (or tubal) pregnancy. The majority of ectopic pregnancies occur in the fallopian tubes (95%); they may also occur in the uterine muscle (1–2%), the abdomen (1–2%), the ovaries (less than 1%), and the cervix (less than 1%).

As an ectopic pregnancy progresses, the fallopian tubes are unable to contain the growing embryo and may rupture. A ruptured ectopic pregnancy is considered a medical emergency as it can cause significant hemorrhaging (excessive bleeding). If an ectopic pregnancy is diagnosed early (i.e., before rupture has occurred), it may be possible to manage medically; the drug methotrexate targets rapidly dividing fetal cells, preventing the fetus from developing further. If medicinal management is not possible or has failed, surgical intervention may be necessary. A salpingostomy may then be performed to remove the pregnancy.

Salpingostomy may also be performed in an effort to restore fertility to a woman whose fallopian tubes have been damaged, such as by adhesions (bands of scar tissue that may form after surgery or trauma). In the case of hydrosalpinx, a condition in which a tube becomes blocked and filled with fluid, a salpingostomy may be performed to create a new tubal ostium (opening).

### Demographics

Ectopic pregnancy occurs in approximately 2% of all pregnancies. Once a woman has an ectopic pregnancy, she has an increased chance (10–25%) of having another. Women between the ages of 25 and 34 have a higher incidence of ectopic pregnancy, although the mortality rate among women over the age of 35 is 2.5–5.9 times higher. Minority women are also at an increased risk of ectopic pregnancy-related death.

### Description

Salpingostomy may be performed via laparotomy or **laparoscopy**, under general or regional anesthesia. A laparotomy is an incision made in the abdominal wall through which the fallopian tubes are visualized. If the tube has already ruptured as a result of an ectopic pregnancy, a salpingectomy will be performed

**A tubal or ectopic pregnancy can be removed in several ways. If the Fallopian tube is ruptured (A), the tube is tied off on both sides, and the embryo removed. If the tube is intact, the embryo can be pulled out the end of the tube (C), or tube can be cut open and the contents removed (D).** (Illustration by GGS Information Services. Cengage Learning, Gale.)

to remove the damaged fallopian tube. If rupture has not occurred, a drug called vasopressin is injected into the fallopian tube to minimize the amount of bleeding. An incision (called a linear salpingostomy) is made through the wall of the tube in the area of the ectopic pregnancy. The products of conception are then flushed out of the tube with an instrument called a suction-irrigator. Any bleeding sites are treated by suturing or by applying pressure with forceps. The incision is not sutured but instead left to heal on its own (called closure by secondary intent). The abdominal wall is then closed.

A neosalpingostomy is similar to a linear salpingostomy but is performed to treat a tubal blockage (e.g., hydrosalpinx). An incision is made to create a new opening in the fallopian tube; the tissue is folded over and

stitched into place. The new hole, or ostium, replaces the normal opening of the fallopian tube through which the egg released by an ovary each menstrual cycle is collected.

Salpingostomy may also be performed laparoscopically. With this surgery, a tube (called a laparoscope) containing a tiny lens and light source is inserted through a small incision in the navel. A camera can be attached that allows the surgeon to see the abdominal cavity on a video monitor. The salpingostomy is then performed with instruments inserted through **trocars**, small incisions of 0.2–0.8 in (0.5–2 cm) made through the abdominal wall.

An advantage of laparoscopic salpingostomy is that the operation is less invasive, thus recovery time is quicker and less painful as compared to a

## KEY TERMS

**Adhesions**—Bands of scar tissue that may form after surgery or trauma.

**Hydrosalpinx**—A condition in which a fallopian tube becomes blocked and filled with fluid.

**Methotrexate**—A drug that targets rapidly dividing fetal cells, preventing a fetus from developing further.

**Salpingectomy**—The surgical removal of a fallopian tube.

laparotomy; the average duration of recovery following laparoscopy is 2.4 weeks, compared to 4.6 weeks for laparotomy. An abdominal incision, on the other hand, allows the surgeon a better view of and easier access to the pelvic organs. Several studies have indicated a reduced rate of normal pregnancy after salpingostomy by laparoscopy versus laparotomy.

## Diagnosis/Preparation

It has been estimated that 40–50% of ectopic pregnancies are incorrectly diagnosed when first presenting to emergency room medical personnel. Often the symptoms of ectopic pregnancy are confused with other conditions such as miscarriage or pelvic inflammatory disease. Diagnosis is usually based on presentation of symptoms, a positive pregnancy test, and detection of a pregnancy outside of the uterus by means of ultrasonography (using a machine that transmits high frequency sound waves to visualize structures in the body).

Diagnosis of hydrosalpinx or other defects of the fallopian tubes may be done surgically, using a laparoscope to visualize the fallopian tubes. Alternatively, a hysterosalpingogram may be performed, in which the uterus is filled with a dye and an x ray is taken to see if the dye flows through the fallopian tubes.

## Aftercare

If performed through an abdominal incision, a salpingostomy requires three to six weeks for full recovery. If salpingostomy is performed laparoscopically, the recovery time can be much shorter (an average of 2.4 weeks). There may be some discomfort around the incision for the first few days after surgery, but most women are walking by the third day. Within a month or so, patients can gradually resume normal activities such as driving, exercising, and working.

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

Salpingostomies are usually performed in a hospital operating room by a surgeon or gynecologist, a medical doctor who has completed specialized training in the areas of women's general health, pregnancy, labor and childbirth, prenatal testing, and genetics.

## Risks

Complications associated with the surgical procedure include reaction to anesthesia, excessive bleeding, injury to other organs, and infection. With an ectopic pregnancy, there is a chance that not all of the products of conception will be removed and that the persistent tissue will continue growing. If this is the case, further treatment will be necessary.

## Normal results

In the case of ectopic pregnancy, the products of conception will be removed without significantly impairing fertility. If salpingostomy is being performed to restore fertility, the procedure will increase a woman's chance of conceiving without resorting to artificial reproductive techniques.

## Morbidity and mortality rates

Abdominal pain occurs in 97% of women with an ectopic pregnancy, vaginal bleeding in 79%, abdominal tenderness in 91%, and infertility in 15%. Persistent ectopic pregnancy after surgical treatment occurs in 5–10% of cases. Ectopic pregnancy accounts for 10–15% of all maternal deaths; the mortality rate for ectopic pregnancy is approximately one in 2,500 cases.

## Alternatives

Some ectopic pregnancies may be managed expectantly (allowing the pregnancy to progress to see if it will resolve on its own). This may occur in up to 25% of ectopic pregnancies. There is, of course, a chance that the fallopian tube will rupture during the period of observation. Treatment with methotrexate is gaining popularity and has been shown to have success rates similar to laparoscopic salpingostomy if multiple doses are given and the patient is in stable condition. Salpingectomy is another surgical option and is indicated if a tube has ruptured or is seriously damaged.

## QUESTIONS TO ASK THE DOCTOR

- Why is a salpingostomy being recommended?
- How will the procedure be performed?
- If an ectopic pregnancy is suspected, how will the diagnosis be confirmed?
- What alternatives to salpingostomy are available to me?

Saphenous vein bypass see **Peripheral vascular bypass surgery**

## Scar revision surgery

### Definition

Scar revision surgery refers to a group of procedures that are done to partially remove scar tissue following surgery or injury, or to make the scar(s) less noticeable. The specific procedure that is performed depends on the type of scar; its cause, location, and size; and the characteristics of the patient's skin.

### Purpose

Scar revision surgery is performed to improve the appearance of the patient's face or other body part, but it is also done to restore or improve functioning when the formation of a scar interferes with the movement of muscles and joints. The shortening or tightening of the skin and underlying muscles that may accompany scar formation is known as contracture. Contractures may interfere with range of motion and other aspects of joint functioning, as well as deform the shape of the hand or other body part. Contractures in the face often affect the muscles that control facial expressions.

Scar revision surgery may be considered as either a cosmetic procedure or a **reconstructive surgery**, depending on whether the patient's concern is primarily related to appearance or whether contractures have also affected functioning. Some insurance companies will cover the cost of scar revision surgery if the scarring resulted from injury. Patients who are considering scar revision surgery should consult their insurance carriers to learn whether their condition may be covered. According to the American Academy of Facial Plastic and Reconstructive Surgery (AAFPRS), the average cost for scar revision surgery on the face is \$1,135, compared to \$1,376 for **dermabrasion**, \$149 for microdermabrasion and \$2,484 for **laser skin resurfacing**.

### Demographics

The demographics of scar revision are difficult to establish precisely because of the number of different procedures that are grouped under this heading and the different types of scars that they are intended to treat. In addition, although dermabrasion and laser resurfacing of the skin are often described as surgical methods of scar treatment to distinguish them from medical modalities, they are usually listed separately in statistical tables. According to the American Society of Plastic Surgeons (ASPS), in 2006 the number of procedures, by type, were as follows: 164,684 for scar

## KEY TERMS

**Collagen**—A type of protein found in connective tissue that gives it strength and flexibility.

**Contracture**—A condition in which the skin and underlying muscles shorten and tighten as the result of the formation of scar tissue or a disorder of the muscle fibers.

**Dermabrasion**—Planing of the skin done by a mechanical device, most commonly fine sandpaper or a wire brush.

**Epidermis**—The outermost layer of the skin.

**Flap**—A piece of tissue used for grafting that has kept its own blood supply.

**Hypertrophic**—A type of thick scar that is raised above the surface of the skin, usually caused by increasing or prolonging the inflammation stage of wound healing.

**Keloid**—A raised, irregularly shaped scar that gradually increases in size due to the overproduction of collagen during the healing process. The name comes from a Greek word that means “crablike.”

**Microdermabrasion**—A technique for skin resurfacing that uses abrasive crystals passed through a hand piece to even out skin irregularities.

**Nonablative**—Not requiring removal or destruction of the epidermis. Some techniques for minimizing scars are nonablative.

revision; 69,300 for dermabrasion; 262,926 for laser resurfacing; and 816,774 for microdermabrasion.

The female to male ratio for scar revision surgery is about four to three, whereas women are almost five times as likely as men to have laser skin resurfacing and almost 13 times as likely to have a microdermabrasion procedure. Most patients who have scar revision surgery are between 15 and 39, although a significant number choose to undergo this type of surgery in their 40s and 50s.

It is difficult to compare scar revision surgery with other treatments across ethnic and racial groups because skin color is a factor in the effectiveness of some forms of therapy. In addition, some types of scars—particularly keloids—are more likely to form in darker skin. On the whole, it is estimated that between 4.5% and 16% of the United States population is affected by keloids and hypertrophic scars. These are the most difficult scars to treat, and are discussed in further detail below.

## Description

### *Scar formation*

A description of the process of scar formation may be helpful in understanding scar revision surgery and other procedures intended to improve the appearance of scarred skin. There are three phases in the formation of a scar:

- **Inflammation.** This phase begins right after the injury and lasts until the wound is closed. It is the body’s way of preventing infection, because a wound is not sterile until it is covered by a new outer layer of skin.
- **Transitional repair.** Scar tissue is formed during this phase to hold the wound together. The length of this phase depends on the severity of the injury.
- **Maturation.** This phase usually begins about seven to 12 weeks after the injury occurs. It is also the phase in which problem scars appear. Under normal conditions, a repair process takes place in which the development of new skin is combined with breaking down the scar tissue that was formed in the second phase of healing. A problem scar is likely to develop when the repair process is interrupted or disturbed.

### *Causes and types of problem scars*

Problem scars may result from inflammatory diseases—particularly acne; trauma, including cuts and burns; previous surgery; and a genetic predisposition for the skin to overreact to injury. Tension on the skin around the wound, foreign material in the wound, infection, or anything that delays closure of the wound may also contribute to scar formation.

The most difficult types of scars to treat are characterized by overproduction of collagen, which is the extracellular protein found in connective tissue that gives it strength and flexibility. The two types of scars that are most often considered for treatment are keloids and hypertrophic scars. Keloids are shiny, smooth benign tumors that arise in areas of damaged skin and look like irregular growths in the wound area. Hypertrophic scars, on the other hand, are thick, ropy-textured scars that are often associated with contractures.

Keloids can be distinguished from hypertrophic scars by the following characteristics:

- **Timing.** Hypertrophic scars usually begin to form within weeks of the injury, whereas keloids may not appear until a year later.
- **Growth pattern.** Hypertrophic scars do not continue to grow after they form, and remain within the original area of injury. Keloids continue to grow and spread outward into normal tissue.

- Role of genetic factors. Keloids tend to run in families, whereas hypertrophic scars do not.
- Racial and age distribution. Keloids occur more frequently in persons with darker skin than in fair-skinned persons. They are also more likely to develop during adolescence and pregnancy, which are periods of high hormone production.
- Recurrence. Hypertrophic scars may fade with time and do not recur. Keloids, on the other hand, may recur even after surgical removal.
- Collagen structure. The collagen fibers in a hypertrophic scar are shorter and generally arranged in a wavelike pattern, whereas the collagen fibers in keloids tend to be randomly arranged.

### *Surgical approaches to scar revision*

The treatment of scars is highly individualized. Most plastic surgeons use a variety of nonsurgical and surgical approaches to improve the appearance of scars. In addition, patients might need several different surgical procedures if their scar revisions require a series of operations at different stages of the healing process.

**SURGICAL EXCISION.** Surgical excision is a procedure in which the surgeon shaves down and cuts out scar tissue to reduce the size of the scar. This technique is most commonly used on large scars that cannot be treated adequately with medications or other nonsurgical means. When excision is done in stages, it is referred to as “serial excision.” This is performed if the area of the scar is too large to remove at one time without distorting nearby skin.

**FLAPS, GRAFTS, AND ARTIFICIAL SKIN.** Flaps, grafts, and artificial skin are used to treat contractures and large areas of scarring resulting from burns and other traumatic injuries. When there is not enough skin at the site of the injury to cover an incision made to remove scar tissue, the surgeon implants a skin graft or flap after cutting out the scar tissue itself. Skin grafts are thin layers of skin that are removed from another part of the patient’s body and carefully matched to the color and texture of the face or other area where the graft is to be placed. A skin flap is a full-thickness piece of tissue with its own blood supply that is taken from a site as close as possible to the scarred area.

Dermal regeneration templates, often called “artificial skin,” are used to treat people with contracture scars or severe burns. These devices were approved by the Food and Drug Administration (FDA) in April 2002. The templates are made of two layers of material, a bottom layer composed of collagen derived

from cows and a top layer made of silicone. To use the artificial skin, the surgeon first removes all the burned skin or scar tissue from the patient’s wound. The collagen layer, which is eventually absorbed, allows the patient’s body to start growing new skin while the silicone layer closes and protects the wound. After 14–21 days, the silicone layer can be removed and a very thin graft of the patient’s own skin is applied to the surface of the wound. The advantages of using a dermal regeneration template are that it lowers the risk of infection and minimizes the amount of tissue that must be removed from the patient’s other body sites.

**Z-PLASTY AND W-PLASTY.** Z-plasty and W-plasty are surgical techniques used to treat contractures and to minimize the visibility of scars by repositioning them along the natural lines and creases in the patient’s skin. They are not usually used to treat keloids or hypertrophic scars. In Z-plasty, the surgeon makes a Z-shaped incision with the middle line of the Z running along the scar tissue. The flaps of skin formed by the other lines of the Z are rotated and sewn into a new position that reorients the scar about 90 degrees. In effect, the Z-plasty minimizes the appearance of the scar by breaking up the straight line of the scar into smaller units.

A W-plasty is similar to a Z-plasty in that the goal of the procedure is to minimize the visibility of a scar by turning a straight line into an irregular one. The surgeon makes a series of short incisions to form a zigzag pattern to replace the straight line of the scar. The primary difference between a Z-plasty and a W-plasty is that a W-plasty does not involve the formation and repositioning of skin flaps. A variation on the W-plasty is known as the geometric broken line closure, or GBLC.

**LASER SKIN RESURFACING AND DERMABRASION.** Skin resurfacing and dermabrasion are techniques used to treat acne scars or to smooth down scars with raised or uneven surfaces. They are known as ablative skin treatments because they remove the top layer of skin, or the epidermis. In dermabrasion, the surgeon moves an instrument with a high-speed rotating wheel over the scar tissue and surrounding skin several times in order to smooth the skin surface down to the lowest level of scarring. Laser skin resurfacing involves the use of a carbon dioxide or Er:YAG laser to evaporate the top layer of skin and tighten the underlying layer. Keloid or hypertrophic scars are treated with a pulsed dye laser. Dermabrasion or laser resurfacing can be used about five weeks after a scar excision to make the remaining scar less noticeable.

Laser skin resurfacing, however, is less popular than it was in the late 1990s because of increasing awareness of its potential complications. The skin of patients who have undergone laser skin resurfacing takes several months to heal, often with considerable discomfort as well as swelling and reddish discoloration of the skin. In addition, there is a 33–85% chance that changes in the color of the skin will be permanent; the risk of permanent discoloration is higher for patients with darker skin. As of 2003, some plastic surgeons are recommending laser resurfacing only for patients with deep wrinkles or extensive sun damage who are willing to accept the pain and permanent change in skin color.

### Diagnosis/Preparation

Preparation for scar revision surgery includes the surgeon's assessment of the patient's psychological stability as well as the type and extent of potential scar tissue. Many patients respond to scarring following trauma with intense anger, particularly if the face is disfigured or their livelihood is related to their appearance. Some people are impatient to have the scars treated as quickly as possible, and may have the idea that revision surgery will restore their skin to its original condition. During the initial interview, the surgeon must explain that scar revision may take months or years to complete; that some techniques essentially replace one scar with another, rather than remove all scar tissue; and that it is difficult to predict the final results in advance. Most plastic surgeons recommend waiting at least six months, preferably a full year, for a new scar to complete the maturation phase of development. Many scars will begin to fade during this period of time, and others may respond to more conservative forms of treatment.

Good candidates for scar revision surgery are people who have a realistic understanding of its risks as well as its benefits, and equally realistic expectations of its potential outcomes. On the other hand, the following are considered psychological warning signs:

- The patient is considering scar revision surgery to please someone else—most often a spouse or partner.
- The patient has a history of multiple cosmetic procedures and/or complaints about previous surgeons.
- The patient has an unrealistic notion of what scar revision surgery will accomplish.
- The patient seems otherwise emotionally unstable.

In addition to discussing the timing and nature of treatments, the surgeon will take a careful medical history, noting whether the patient is a heavy smoker or has a family history of keloids, as well as other

disorders that may influence the healing of scar tissue. These disorders include diabetes, lupus, scleroderma, and other disorders that compromise body's immune system.

### Aftercare

Aftercare following Z-plasty or surgical removal of a scar is relatively uncomplicated. The patient is given pain medication, told to rest for a day or two at home, and advised to avoid any activities that might put tension or pressure on the new incision(s). Most patients can return to work on the third day after surgery. The most important aspect of long-term aftercare is protecting the affected area from the sun because the surgical scar will take about a year to mature and is only about 80% as strong as undamaged skin. Sunlight can cause burns, permanent redness, loss of pigment in the skin, and breakdown of the collagen that maintains the elasticity of the skin.

Aftercare following the use of skin grafts, flaps, or dermal regeneration templates begins in the hospital with standard postoperative patients care. If sutures have been used, they are usually removed three to four days after surgery on the face and five to seven days after surgery for incisions elsewhere on the body. Patients are usually asked to return to the hospital at regular intervals so that the graft sites can be monitored. If artificial skin has been used, the patients must keep the site absolutely dry, which may require special precautions or restrictions on bathing or showering.

Aftercare for some patients includes going for psychotherapy or joining a support group to deal with emotions related to disfigurement and scar treatment.

### Risks

Scar revision surgery carries the same risks as other surgical procedures under anesthesia, such as bleeding, infection at the incision site, and an adverse reaction to the anesthetic. The chief risk specific to this type of surgery is that the scar may grow, change color, or otherwise become more noticeable. Some plastic surgeons use the "90–10 rule," which means that there is a 90% chance that the scar will look better after surgery; a 9% chance that it will look about the same; and a 1% chance that it will look significantly worse.

### Normal results

Normal results of scar revision surgery and associated nonsurgical treatments are a less noticeable scar.

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

Scar revision surgery is a specialized procedure performed only by a qualified plastic surgeon. Plastic surgeons are physicians (with M.D. or D.O. [doctors of osteopathy]) who have completed three years of general surgical training, followed by two to three years of specialized training in plastic surgery.

Scar revision may be conducted either in a hospital or in an outpatient clinic that specializes in plastic surgery. Scar revision surgery that involves skin grafts and flaps, however, is usually done in a hospital as an inpatient procedure. Microdermabrasion, chemical peels, steroid injections, pressure wraps, and silicone treatments may be performed in the surgeon's office.

### Morbidity and mortality rates

Mortality rates for scar revision surgery are very low. Rates of complications depend on the specific technique that was used, the condition of the patient's general health, and genetic factors affecting the condition of the patient's skin.

### Alternatives

There are a number of nonsurgical treatments that can be used before, after, or in place of scar revision surgery.

#### Drugs

Medications may be used during the initial inflammatory phase of scar formation, as well as therapy for such specific skin disorders as acne. Keloids are often treated by direct injections of **corticosteroids** to reduce itching, redness, and burning; steroid treatment may also cause the keloid to shrink. Corticosteroid injections, gels, or tapes impregnated with medication are also used after scar excisions and Z-plasty to prevent recurrence or formation of hypertrophic scars. Acne scars are treated with oral **antibiotics** or isotretinoin.

#### *Massage, wraps, radiation, and nonablative treatments*

The most conservative treatments of scar tissue include several techniques that help to minimize scar formation and improve the appearance of scars that

## QUESTIONS TO ASK THE DOCTOR

- Am I a candidate for treatment by a nonsurgical method of scar revision?
- What treatment technique(s) would be best for my scar?
- How long should I wait before scar revision surgery?
- What are the risks of the specific procedures you are recommending in my case?

existing already. The simplest approach is repeated massage of the scarred area with cocoa butter or vitamin E preparations. Burn scars are treated typically with the application of pressure **dressings**, which restrict movement of the affected area and provide insulation. Another technique that is often used is silicone gel sheeting. The sheeting is applied to the scarred area, and remains for a minimum of 12 hours a day over a period of three to six months. It is effective in improving the appearance of keloids in about 85% of cases.

Keloids that do not respond to any other form of treatment may be treated with low-dose radiation therapy.

Nonablative treatments, which do not remove the epidermal layer of skin, include microdermabrasion and superficial chemical peels. Microdermabrasion, the use of which has increased widely since 2000, is a technique for smoothing the skin. During this procedure, the physician uses a handheld instrument that buffs the skin with aluminum oxide crystals; skin flakes are removed through a vacuum tube. Microdermabrasion does not remove deep wrinkles or extensive scar tissue, but can make scars somewhat less noticeable without the risk of serious side effects. Mild chemical peels, such as those made with alpha-hydroxy acid (AHA), are used sometimes to treat acne scars or uneven skin pigmentation resulting from other types of scar revision treatment.

#### *Camouflage*

Scars on the face and legs can often be covered with specially formulated cosmetics that even out the color of the surrounding skin and help to make the scar less noticeable. Some of these preparations are available in waterproof formulations for use during swimming and other athletic activities during which one perspires.

## Scleral buckling

### Definition

Scleral buckling is a surgical procedure in which a piece of silicone plastic or sponge is sewn onto the sclera at the site of a retinal tear to push the sclera toward the retinal tear. The buckle holds the retina against the sclera until scarring seals the tear. It also prevents fluid leakage which could cause further retinal detachment.

### Purpose

Scleral buckling is used to reattach the retina if the break is very large or if the tear is in one location. It is also used to seal breaks in the retina.

### Demographics

Retinal detachment occurs in 25,000 Americans each year. Patients suffering from retinal detachments are commonly nearsighted, have had eye surgery, experienced ocular trauma, or have a family history of retinal detachments. Retinal detachments also are common after cataract removal. White males are at a higher risk, as are people who are middle-aged or older. Patients who already have had a retinal detachment also have a greater chance for another detachment.

Some conditions, such as diabetes or Coats's disease in children, make people more susceptible to retinal detachments.

### Description

Scleral buckling is performed in an **operating room** under general or local anesthetic. Immediately before the procedure, patients are given eye drops to dilate the pupil to allow better access to the eye. The patient is given a local anesthetic. After the eye is numbed, the surgeon cuts the eye membrane, exposing the sclera. If bleeding or inflammation blocks the surgeon's view of the retinal detachment or hole, he or she may perform a vitrectomy before scleral buckling.

Vitrectomy is necessary only in cases in which the surgeon's view of the damage is hindered. The surgeon makes two incisions into the sclera, one for a light probe and the other for instruments to cut and aspirate. The surgeon uses a tiny, guillotine-like device to remove the vitreous, which he or she then replaces with saline. After the removal, the surgeon may inject air or gas to hold the retina in place.

After the surgeon is able to see the retina, he or she will perform one of two companion procedures.

- **Laser photocoagulation.** The laser is used when the retinal tear is small or the detachment is slight. The surgeon points the laser beam through a contact lens to burn the area around the retinal tear. The laser creates scar tissue that will seal the hole and prevent leakage. It requires no incision.
- **Cryopexy.** Using a freezing probe, the surgeon freezes the outer surface of the eye over the tear or detachment. The inflammation caused by the freezing leads to scar formation that seals the hole and prevents leakage. Cryopexy is used for larger holes or detachments, and for areas that may be hard to reach with a laser.

In a scleral buckling procedure, one of the eye's rectus muscles are severed to gain access to the sclera (A). The sclera is cut open (B), and an electrode is applied to the area of retinal detachment (C). A silicone buckle is threaded into place beneath the rectus muscles (D), and the severed muscle is repaired. (Illustration by GGS Information Services. Cengage Learning, Gale.)

After the surgeon has performed laser photocoagulation or cryopexy, he or she indents the affected area of the sclera with silicone. The silicone, either in the form of a sponge or buckle, closes the tear and reduces the eyeball's circumference. This reduction prevents further pulling and separation of the vitreous. Depending on the severity of the detachment or hole, a buckle may be placed around the entire eyeball.

When the buckle is in place, the surgeon may drain subretinal fluid that might interfere with the retina's reattachment. After the fluid is drained, the surgeon will suture the buckle into place and then cover it with

the conjunctiva. The surgeon then inserts an antibiotic (drops or ointment) into the affected eye and patches it.

For less severe detachments, the surgeon may choose a temporary buckle that will be removed later. Usually, however, the buckle remains in place for the patient's lifetime. It does not interfere with vision. Scleral buckles in infants, however, will need to be removed as the eyeball grows.

### Diagnosis/Preparation

Retinal detachment is considered an emergency situation. In the case of acute onset detachment, the

## KEY TERMS

**Conjunctiva**—The mucous membrane that lines the visible part of the eye and the inner eyelid.

**Glaucoma**—Disease of the eye characterized by increased pressure of the fluid inside the eye. Untreated, glaucoma can lead to blindness.

**Sclera**—The outer part of the eyeball that creates the visible white of the eye and surrounds the optic nerve at the back of the eyeball.

**Vitreous**—Between the lens and the retina, this area contains a clear jelly called the vitreous humor.

longer it takes to repair the detachment, the less chance of successful reattachment. Usually the patient sees floating spots and experiences peripheral visual field loss. Patients commonly describe the vision loss as having someone pull a shade over their eyes. In extreme cases, patients may lose vision completely.

An ophthalmologist or optometrist will take a complete medical history, including family history of retinal detachment and any recent ocular trauma. In addition to performing a general eye exam, which includes a slit lamp examination, examination of the macula and lens evaluation, physicians may perform the following tests to determine the extent of retinal detachment:

- echography
- 3-mirror contact lens/panfunduscopy
- scleral indentation

Small breaks in the retina will not require surgery, but patients with acute onset detachment require reattachment in 24–48 hours. Chronic retinal detachments should be repaired within one week.

Because this is usually an emergency procedure, there is no long-term preparation. Patients are required to fast for at least six hours before surgery.

### Aftercare

Immediately following the surgery, patients will need help with meals and walking. Some patients must remain hospitalized for several days. However, many scleral buckling procedures are performed on an outpatient basis.

After release from the hospital, patients should avoid heavy lifting or strenuous **exercise** that could increase intraocular pressure. Rapid eye movements should also be avoided; reading may be prohibited

until the surgeon gives permission. Sunglasses should be worn during the day and an eye patch at night. Pain, redness, and a scratchy sensation in the eyes also may occur after surgery. Ice packs may be applied if the conjunctiva swells. Patients may take pain medication, but should check with their physician before taking any over-the-counter medication.

Excessive pain, swelling, bleeding, discharge from the eye or decreased vision is not normal, and should immediately be reported to the physician.

If a vitrectomy was performed in conjunction with the scleral buckling, patients must sleep with their heads elevated. They also must avoid air travel until the air bubble is absorbed.

After scleral buckling, patients will use dilating, antibiotic, or corticosteroid eye drops for up to six weeks to decrease inflammation and the chance of infection. Best visual acuity cannot be determined for at least six to eight weeks after surgery. Driving may be prohibited or restricted while vision stabilizes. At the six-to-eight week postoperative visit, physicians determine if the patient needs corrective lenses or stronger prescription lenses. Full vision restoration depends on the location and severity of the detachment.

### Risks

Complications are rare but may be severe. In some instances, patients lose sight in the affected eye or lose the entire eye.

Scar tissue, even pre-existing scar tissue, may interfere with the retina's reattachment and the scleral buckling procedure may have to be repeated. Scarring, along with infection, is the most common complication.

Other possible but infrequent complications include:

- bleeding under the retina
- cataract formation
- double vision
- glaucoma
- vitreous hemorrhage

Patients may also become more nearsighted after the procedure. In some instances, although the retina reattaches, vision is not restored.

### Normal results

The National Institutes of Health reports that scleral buckling has a success rate of 85–90%. Restored vision depends largely on the location and extent of the detachment, and the length of time before the detachment was repaired. Patients with a

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

Scleral buckling can be performed by a general ophthalmologist, an M.D. who specializes in treatment of the eye. Even more specialized ophthalmologists, vitreo-retinal surgeons who specialize in diseases of the retina, may be called upon for serious cases.

The surgery is usually performed in hospital settings. Because of the delicacy of the procedure, sometimes an overnight hospital stay is required. Less severe retinal detachments can be treated on an outpatient basis at surgery centers.

peripheral detachment have a quicker recovery than those patients whose detachment was located in the macula. The longer the patient waits to have the detachment repaired, the worse the prognosis.

### Morbidity and mortality rates

The danger of mortality and loss of vision depends on the cause of the retinal detachment. Patients with Marfan syndrome, pre-eclampsia, and diabetes, for example, are more at risk during the scleral buckling procedure than a patient in relatively good health. The risk of surgery also rises with the use of **general anesthesia**. Scleral buckling, however, is considered a safe, successful procedure.

Severe infections that are left untreated can cause vision loss, but following the prescribed regimen of eye drops and follow-up treatment by the physician greatly minimizes this risk.

### Alternatives

Vitrectomy is sometimes performed alone to treat retinal detachments. Laser photocoagulation and cryopexy also may be used to treat less serious tears. The more common alternative, however, is pneumatic retinopexy, which is used when the tear is located in the upper portion of the eye. The surgeon uses cryopexy to freeze the area around the tear, then removes a small amount of fluid. When the fluid is drained and the eye softened, the surgeon injects a gas bubble into the vitreous cavity. As the gas bubble expands, it seals the retinal tear by pushing the retina against the choroid. Eventually, the bubble will be absorbed.

## QUESTIONS TO ASK THE DOCTOR

How many scleral buckling procedures have you performed?

Could other treatments be an option?

Will I have to stay in the hospital?

Will my sight be completely restored?

What is the probability of having another retinal detachment in the same eye?

Am I likely to have a retinal detachment in my unaffected eye?

The patient is required to remain in a certain position for at least a few days after surgery while the bubble helps seal the hole. Pneumatic retinopexy also is not as successful as scleral buckling. Complications include recurrent retinal detachments and the chance of gas getting under the retina.

## Sclerostomy

### Definition

A sclerostomy is a procedure in which the surgeon makes a small opening in the outer covering of the eyeball to reduce intraocular pressure (IOP) in patients with open-angle glaucoma. It is classified as a type of glaucoma filtering surgery. The name of the surgery comes from the Greek word for “hard,” which describes the tough white outer coat of the eyeball, and the Greek word for “cutting” or “incision.”

### Purpose

Sclerostomies are usually performed to reduce IOP in open-angle glaucoma patients who have not been helped by less invasive forms of treatment, specifically medications and **laser surgery**. In some cases—most commonly patients who are rapidly losing their vision or who cannot tolerate glaucoma medications—an ophthalmologist (eye specialist) may recommend a sclerostomy without trying other forms of treatment first.

As of 2003, glaucoma is not considered a single disease but rather a group of diseases characterized by three major characteristics: elevated intraocular pressure (IOP) caused by an overproduction of aqueous humor in the eye or by resistance to the normal outflow of fluid; atrophy of the optic nerve; and a resultant loss of visual field. A sclerostomy works to reduce the IOP by improving the outflow of aqueous humor. Between 80% and 90% of aqueous humor leaves the eye through the trabecular meshwork while the remaining 10–20% passes through the ciliary muscle bundles. A sclerostomy allows the fluid to collect under the conjunctiva, which is the thin membrane lining the eyelids, to form a filtration bleb.

### Demographics

In 1995, the World Health Organization (WHO) reported that over five million people around the world have lost their sight due to complications of glaucoma; about 120,000 Americans are blind as a result of glaucoma. According to the National Eye Institute (NEI), nearly three million people in the United States have the disorder; however, nearly half are unaware that they have it. Primary open-angle glaucoma (POAG) accounts for 60–70% of cases. “Primary” means that the glaucoma is not associated with a tumor, injury to the eye, or other eye disorder.

Although glaucoma can occur at any age, it is most common in adults over 35. One major study reported that less than 1% of the United States population between 60 and 64 suffer from POAG. The rate rises to 1.3% for persons between 70 and 74, however, and rises again to 3% for persons between 80 and 84.

With regard to race, African-Americans are four times as likely to develop glaucoma as Caucasians, and six to eight times more likely to lose their sight to the disease. African Americans also develop glaucoma at earlier ages; while everyone over age 60 is at increased risk for POAG, the risk for African Americans rises sharply after age 40. A 2001 study reported that the rate for Mexican Americans lies between the rate of POAG in African Americans and that in Caucasians. Mexican Americans, however, are more likely to suffer from undiagnosed glaucoma—62% as compared to 50% for other races and ethnic groups in the United States. In addition, the rate of POAG in Mexican Americans was found to rise rapidly after age 65; in the older age groups, it approaches the rates reported for African Americans. Among Caucasians, people of Scandinavian, Irish, or Russian ancestry are at higher risk of glaucoma than people from other ethnic groups.

The question of a sex ratio in open-angle glaucoma is debated. Three studies done in the United States between 1991 and 1996 reported that the male to female ratio for open-angle glaucoma is about one to one. Three other studies carried out in the United States, Barbados, and the Netherlands, however, found that the male to female ratio was almost two to one. A 2002 study from western Africa reported a male to female ratio of 2.26 to one. It appears that further research is needed in this area.

### Description

Most sclerostomies are performed as outpatient procedures under **local anesthesia**. In some cases the

## KEY TERMS

**Angle**—The open point in the anterior chamber of the eye at which the iris meets the cornea.

**Aqueous humor**—The watery fluid produced in the eye that ordinarily leaves the eye through the angle of the anterior chamber and Schlemm's canal.

**Atrophy**—Wasting away or degeneration. Atrophy of the optic nerve is one of the defining characteristics of glaucoma.

**Bleb**—A thin-walled auxiliary drain created on the outside of the eyeball during filtering surgery for glaucoma. It is sometimes called a filtering bleb.

**Conjunctiva**—The thin membrane that lines the eyelids and covers the visible surface of the sclera.

**Cornea**—The transparent front portion of the exterior cover of the eye.

**Endophthalmitis**—An infection on the inside of the eye, which may result from an infected bleb. Endophthalmitis can result in vision loss.

**Glaucoma**—A group of eye disorders characterized by increased fluid pressure inside the eye that eventually damages the optic nerve. As the cells in the optic nerve die, the patient gradually loses vision.

**Gonioscopy**—A technique for examining the angle between the iris and the cornea with the use of a special mirrored lens applied to the cornea.

**Hyphema**—Blood inside the anterior chamber of the eye. Hyphema is one of the risks associated with sclerostomies.

**Hypotony**—Intraocular fluid pressure that is too low.

**Insidious**—Developing in a stealthy and inconspicuous way. Open-angle glaucoma is an insidious disorder.

**Ocular hypertension**—A condition in which fluid pressure inside the eye is higher than normal but the optic nerve and visual fields are normal.

**Open-angle glaucoma**—A form of glaucoma in which fluid pressure builds up inside the eye even though the angle of the anterior chamber is open and looks normal when the eye is examined with a gonioscope. Most cases of glaucoma are open-angle.

**Ophthalmology**—The branch of medicine that deals with the diagnosis and treatment of eye disorders.

**Peripheral vision**—The outer portion of the visual field.

**Schlemm's canal**—A circular channel located at the point where the sclera of the eye meets the cornea. Schlemm's canal is the primary pathway for aqueous humor to leave the eye.

**Sclera**—The tough white fibrous membrane that forms the outermost covering of the eyeball.

**Tonometry**—Measurement of the fluid pressure inside the eye.

**Trabecular meshwork**—The main drainage passageway for fluid to leave the anterior chamber of the eye.

**Visual field**—The total area in which one can see objects in one's peripheral vision while the eyes are focused on a central point.

patient may be given an intravenous sedative to help him or her relax before the procedure.

### *Conventional sclerostomy*

After the patient has been sedated, the surgeon injects a local anesthetic into the area around the eye as well as a medication to prevent eye movement. Using very small instruments with the help of a microscope, the surgeon makes a tiny hole in the sclera as a passageway for aqueous humor. Some surgeons use an erbium YAG laser to create the hole. Most surgeons apply an antimetabolite drug during the procedure to minimize the risk that the new drainage channel will be closed by tissue regrowth. The most common antimetabolites that are used are mitomycin and 5-fluorouracil.

After the surgery, the aqueous humor begins to flow through the sclerostomy hole and forms a small blister-like structure on the upper surface of the eye. This structure is known as a bleb or filtration bleb, and is covered by the eyelid. The bleb allows the aqueous humor to leave the eye in a controlled fashion.

### *Enzymatic sclerostomy*

A newer technique that was first described in 2002 is enzymatic sclerostomy, which was developed at the Weizmann Institute of Science in Israel. In enzymatic sclerostomy, the surgeon applies an enzyme called collagenase to the eye to increase the release of aqueous humor. The collagenase is applied through an applicator that is attached to the eye with tissue **glue** for 22–24 hours and then removed.

According to the researchers, the procedure reduced the intraocular pressure in all patients immediately following the procedure and in 80% of the subjects at one-year follow-up. None of the patients developed systemic complications. Enzymatic sclerostomy is considered experimental as of mid-2003.

## Diagnosis/Preparation

### Diagnosis

Open-angle glaucoma is not always diagnosed promptly because it is insidious in onset, which means that it develops slowly and gradually. Unlike closed-angle glaucoma, open-angle glaucoma rarely has early symptoms. It is usually diagnosed either in the course of an eye examination or because the patient has noticed that they are having problems with their peripheral vision—that is, they are having trouble seeing objects at the side or out of the corner of the eye. In some cases the patient notices that he or she is missing words while reading; having trouble seeing stairs or other objects at the bottom of the visual field; or having trouble seeing clearly when driving. Other symptoms of open-angle glaucoma may include headaches, seeing haloes around lights, or difficulty adjusting to darkness. It is important to diagnose open-angle glaucoma as soon as possible because the vision that has been already lost cannot be recovered. Although open-angle glaucoma cannot be cured, it can be stabilized and controlled in almost all patients. Because of the importance of catching open-angle glaucoma as early as possible, adults should have their eyes examined every two years at least.

**HIGH-RISK GROUPS.** Not everyone is at equal risk for glaucoma. People with any of the risk factors listed below should consult their doctor for advice about the frequency of eye checkups:

- Age over 40 (African Americans) or over 60 (other races and ethnic groups).
- Ocular hypertension. The normal level of IOP is between 11 mm Hg and 21 mm Hg. It is possible for people to have an IOP above 21 mm Hg without signs of damage to the optic nerve or loss of visual field; this condition is referred to as ocular hypertension. Conversely, about one out of six of patients diagnosed with open-angle glaucoma have so-called normal-tension glaucoma, which means that their optic nerve is being damaged even though their IOP is within the “normal” range. Ocular hypertension does, however, increase a person’s risk of developing glaucoma in the future.
- Family history of glaucoma in a first-degree relative. As of 2003, at least six different genes related to glaucoma have been identified.

- An unusually thin cornea (the clear front portion of the outer cover of the eye). A recent National Eye Institute (NEI) study found that patients whose corneas are thinner than 555 microns are three times as likely to develop glaucoma as those whose corneas are thicker than 588 microns.
- Extreme nearsightedness. People who are very nearsighted are two to three times more likely to develop glaucoma than those who are not nearsighted.
- Diabetes.
- History of traumatic injury to the eye or surgery for other eye disorders.
- Use of steroid medications.
- Migraine headaches or sleep-related breathing disorder.
- Male sex.

Some patients should not be treated with filtration surgery. Contraindications for a sclerostomy include cardiovascular disorders and other severe systemic medical problems; eyes that are already blind; or the presence of an intraocular tumor or bleeding in the eye.

**DIAGNOSTIC TESTS.** Ophthalmologists use the following tests to screen patients for open-angle glaucoma:

- Tonometry. Tonometry is a painless procedure for measuring IOP. One type of tonometer blows a puff of pressurized air toward the patient’s eye as the patient sits near a lamp; it measures the changes in the light reflections on the patient’s corneas. Another method of tonometry involves the application of a local anesthetic to the outside of the eye and touching the cornea briefly with an instrument that measures the fluid pressure directly.
- Visual field test. This test measures loss of peripheral vision. In the simplest version of this test, the patient sits directly in front of the examiner with one eye covered. The patient looks at the examiner’s eye and indicates when he or she can see the examiner’s hand. In the automated version, the patient sits in front of a hollow dome and looks at a central target inside the dome. A computer program flashes lights at intervals at different locations inside the dome, and the patient presses a button whenever he or she sees a light. At the end of the test, the computer prints an assessment of the patient’s responses.
- Gonioscopy. Gonioscopy measures the size of the angle in the anterior chamber of the eye with the use of a special mirrored contact lens. The examiner numbs the outside of the eye with a local anesthetic and touches the outside of the cornea with the gonioscopic lens. He or she can use a slit lamp to magnify

what appears on the lens. Gonioscopy is necessary in order to distinguish between open- and closed-angle glaucoma; it can also distinguish between primary and many secondary glaucomas.

- **Ophthalmoscopic examination of the optic nerve.** An ophthalmoscope is an instrument that contains a perforated mirror as well as magnifying lenses. It allows the examiner to view the interior of the eye. If the patient has open-angle glaucoma, the examiner can see a cup-shaped depression in the optic disk.

Newer diagnostic devices include a laser-scanning microscope known as the Heidelberg retinal tomograph (HRT) and **ultrasound** biomicroscopy (UBM). UBM has proved to be a useful method of long-term follow-up of sclerostomies.

### **Preparation**

Preparation for a sclerostomy begins with the patient's decision to undergo incisional surgery rather than continuing to take medications or having repeated laser procedures. Three factors commonly influence the decision: the present extent of the patient's visual loss; the speed of visual deterioration; and the patient's life expectancy.

With regard to the procedure itself, patients may be asked to take oral antibiotic and anti-inflammatory medications for several days prior to surgery.

### **Aftercare**

Patients can use their eyes after filtering surgery, although they should have a friend or relative to drive them home after the procedure. They can go to work the next day, although they will probably notice some blurring of vision in the operated eye for about a month. Patients can carry out their normal activities with the exception of heavy lifting, although they should not drive until their vision has completely cleared. Most ophthalmologists recommend that patients wear their eyeglasses during the day and tape an eye shield over the operated eye at night. They should apply eye drops prescribed by the ophthalmologist to prevent infection, manage pain, and reduce swelling. They should also avoid rubbing, bumping, or getting water into the operated eye. Complete recovery after filtering surgery usually takes about six weeks. Long-term aftercare includes avoiding damage to or infection of the bleb.

It is important for patients recovering from filtering surgery to see their doctor for frequent checkups in the first few weeks following surgery. In most cases the ophthalmologist will check the patient's eye the day after surgery and about once a week for the next several weeks.

### **Risks**

The risks of a sclerostomy include the following:

- **Infection.** Infections may develop in the bleb (blebitis), but may spread to the interior of the eye (endophthalmitis). The symptoms of an infection include pain and redness in the eye, blurred vision, teariness, and a discharge. Infections must be treated promptly, as they can lead to loss of vision.
- **Hyphema.** Hyphema refers to the presence of blood inside the anterior chamber of the eye. Hyphemas are most common within the first two to three days after surgery and are usually treated with corticosteroid medications to reduce inflammation.
- **Suprachoroidal hemorrhage.** A suprachoroidal hemorrhage, or massive bleeding behind the retina, is a serious complication that can occur during as well as after eye surgery.
- **Cataract formation.**
- **Hypotony (low IOP).** If hypotony is not corrected, it can lead to failure of the bleb and eventual cataract formation.
- **Loss of central vision.** This is a very rare complication.
- **Bleb leak or failure.** Blebs can develop leaks at any time from several days after surgery to years later. Bleb failure usually results from inadequate control of the intraocular pressure and a new obstruction of aqueous humor outflow.
- **Closing of the opening in the sclera by new tissue growth.** A sclerostomy can be repeated if necessary.

### **Normal results**

According to the National Eye Institute, sclerostomy is 80–90% effective in lowering intraocular pressure. The success rate is highest in patients who have not had previous eye surgery.

### **Morbidity and mortality rates**

Mortality following a sclerostomy is very low because the majority of procedures are performed under local anesthesia. The most common complications of filtering surgery are cataract formation (30% of patients develop cataracts within five years of a sclerostomy) and closure of the drainage opening requiring additional surgery (10–15% of patients). Bleeding or infection occur in less than 1% of patients.

### **Alternatives**

#### ***Nonpenetrating deep sclerectomy***

There are two surgical alternatives to sclerostomy that are called nonpenetrating deep sclerectomies

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

Sclerostomies are performed by ophthalmologists, who are physicians who have completed four to five years of specialized training following medical school in the medical and surgical treatment of eye disorders. Ophthalmology is one of 24 specialties recognized by the American Board of Medical Specialties.

Sclerostomies are usually done as outpatient procedures, either in the ophthalmologist's office or in an ambulatory surgery center; however, they may also be performed in a hospital with sedation as well as local anesthesia.

because they do not involve entering the anterior chamber of the eye. The first alternative, viscocanalostomy, is a procedure that involves creating a window in Descemet's membrane (a layer of tissue in the cornea) to allow aqueous humor to leave the anterior chamber; and injecting a viscoelastic substance into Schlemm's canal, which is the main pathway for aqueous humor to leave the eye. The viscoelastic helps to keep the canal from scarring shut following surgery.

The second type of nonpenetrating surgery involves implanting a device called the Aquaflow® collagen wick about 0.8 in (2 cm) long under the sclera. The wick keeps open a space created by the surgeon to allow drainage of the aqueous humor. The wick is made of a material that is absorbed by the body within six to nine months, but the drainage pathway remains open after the wick is absorbed. The Aquaflow wick was approved by the Food and Drug Administration (FDA) in July 2001.

Both types of nonpenetrating deep sclerectomies allow patients to recover faster, with fewer complications than traditional sclerostomies. Their drawbacks include a lower success rate and the need for additional procedures to control the patient's IOP. Visco-canalostomy in particular is not as effective in reducing IOP levels as traditional filtering surgery.

### ***Complementary and alternative (CAM) approaches***

Bilberry (European blueberry) extract has been recommended as improving night vision; it was given to pilots during World War II for this reason. There is evidence that 80–160 mg of bilberry extract taken

## QUESTIONS TO ASK THE DOCTOR

- How many sclerostomies have you performed?
- Do you prefer using miniature instruments or a laser, and why?
- What are my chances of developing a cataract if I have this procedure?
- Would you recommend nonpenetrating surgery? Why or why not?

three times a day does improve night vision temporarily. The plant does not have any serious side effects, but it should not be used in place of regular eye examinations or other treatments for glaucoma.

People who support the medicinal use of marijuana have argued that cannabinoids, the active chemical compounds found in the plant, lower intraocular pressure in patients with glaucoma. According to the Glaucoma Research Foundation, however, very high doses of marijuana are required to produce any significant effect on IOP. A Canadian researcher has concluded that the effects of cannabinoids on IOP "...are not sufficiently strong, long lasting or reliable to provide a valid basis for therapeutic use [of marijuana]."

## Sclerotherapy for esophageal varices

### Definition

Sclerotherapy for esophageal varices, also called endoscopic sclerotherapy, is a treatment for esophageal bleeding that involves the use of an endoscope and the injection of a sclerosing solution into veins.

### Purpose

Esophageal varices are enlarged or swollen veins on the lining of the esophagus which are prone to bleeding. They are life-threatening; each episode of bleeding carries a 20-30% risk of **death**. 70% of patients who do not receive treatment for their varices die of bleeding within a year of their first episode of bleeding. Esophageal varices are a complication of portal hypertension, a condition characterized by increased blood pressure in the portal vein resulting from liver disease, such as cirrhosis. Increased pressure causes the veins to balloon outward. The vessels may rupture, causing vomiting of blood and bloody stools.

In most hospitals, sclerotherapy for esophageal varices is the treatment of choice to stop esophageal bleeding during acute episodes, and to prevent further incidences of bleeding. Emergency sclerotherapy is often followed by preventive treatments to eradicate distended esophageal veins.

### Demographics

Bleeding esophageal varices are a serious complication of liver disease. In the United States, at least 50% of people who survive bleeding esophageal varices are at risk of recurrent bleeding during the next one to two years.

## KEY TERMS

**Cirrhosis**—A chronic degenerative liver disease causing irreversible scarring of the liver.

**Endoscope**—An instrument used to examine the inside of a canal or hollow organ. Endoscopic surgery is less invasive than traditional surgery.

**Esophagus**—The part of the digestive canal located between the pharynx (part of the digestive tube) and the stomach. Also called the food pipe.

**Portal hypertension**—Abnormally high pressure within the veins draining into the liver.

**Sclerosant**—An irritating solution that stops bleeding by hardening the blood or vein it is injected into.

**Varices**—Swollen or enlarged veins, in this case on the lining of the esophagus.

## Description

Sclerotherapy for esophageal varices involves injecting a strong and irritating solution (a sclerosant) into the veins and/or the area beside the distended vein. Sclerosant injected directly into the vein causes blood clots to form and stops the bleeding, while sclerosant injected into the area beside the distended vein stops the bleeding by thickening and swelling the vein to compress the blood vessel. Most physicians inject the sclerosant directly into the vein, although injections into the vein and the surrounding area are both effective. Once bleeding has been stopped, the treatment can be used to significantly reduce or destroy the varices.

Sclerotherapy for esophageal varices is performed with the patient awake but sedated. Hyoscine butylbromide (Buscopan) may be administered to freeze the esophagus, making injection of the sclerosant easier. During the procedure, an endoscope is passed through the patient's mouth to the esophagus to allow the surgeon to view the inside. The branches of the blood vessels at or just above where the stomach and esophagus come together, the usual site of variceal bleeding, are located. After the bleeding vein is identified, a long, flexible sclerotherapy needle is passed through the endoscope. When the tip of the needle's sheath is in place, the needle is advanced, and the sclerosant is injected into the vein or the surrounding area. The most commonly used sclerosants are ethanolamine and sodium tetradecyl sulfate. The needle is withdrawn. The procedure is repeated as many times as necessary to eradicate all distended veins.

## Diagnosis/Preparation

A radiologist assesses patients for sclerotherapy based on blood work and liver imaging studies performed using **CT scans**, **ultrasound**, or MRI scans, and in consultation with the treating gastroenterologist, hepatologist, or surgeon. Tests to localize bleeding and detect active bleeding are also performed.

Before a sclerotherapy procedure, the patient's **vital signs** and other pertinent data are recorded, an intravenous line is inserted to administer fluid or blood, and a sedative is prescribed.

## Aftercare

After sclerotherapy for esophageal varices, the patient will be observed for signs of blood loss, lung complications, fever, a perforated esophagus, or other complications. Vital signs are monitored, and the intravenous line maintained. Pain medication is usually prescribed. After leaving the hospital, the patient follows a diet prescribed by the physician, and, if appropriate, can take mild pain relievers.

## Risks

Risks associated with sclerotherapy include complications that can arise from use of the sclerosant or from the endoscopic procedure. Minor complications, which cause discomfort but do not require active treatment or prolonged hospitalization, include transient chest pain, difficulty swallowing, and fever, which usually go away after a few days. Some patients may have allergic reactions to the sclerosant solution. Infection occurs in up to 50% of cases. In 2-10% of patients, the esophagus tightens, but this can usually be treated with dilatation. More serious complications may occur in 10-15% of patients. These include perforation or bleeding of the esophagus and lung problems, such as aspiration pneumonia. Long-term sclerotherapy can also damage the esophagus, and increase the patient's risk of developing cancer.

Patients with advanced liver disease complicated by bleeding are very poor risks for this procedure. The surgery, premedications, and anesthesia may be sufficient to tip the patient into protein intoxication and hepatic coma. The blood in the bowels acts like a high-protein meal and may induce protein intoxication.

## Normal results

Normal sclerotherapy results include the control of acute bleeding if present and the shrinking of the esophageal varices.

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

Sclerotherapy for esophageal varices is performed by a surgeon specialized in gastroenterology or hepatology in a hospital setting, very often as an emergency procedure.

### Morbidity and mortality rates

Sclerotherapy for esophageal varices has a 20–40% incidence of complications and a 1–2% mortality rate. The procedure controls acute bleeding in about 90% of patients, but it may have to be repeated within the first 48 hours to achieve this success rate. During the initial hospitalization, sclerotherapy is usually performed two or three times. Preventive treatments are scheduled every few weeks or so, depending on the patient's risk level and healing rate. Several studies have shown that the risk of recurrent bleeding is much lower in patients treated with sclerotherapy: 30–50% as opposed to 70–80% for patients not treated with sclerotherapy.

### Alternatives

Pharmacological agents are also used in the treatment of esophageal varices. Drugs such as vasopressin and somatostatin are administered to actively bleeding patients on admission, while propranolol, nadolol or subcutaneous octreotide are used to prevent subsequent bleeding after successful endoscopic variceal eradication. Vasopressin or vasopressin with nitroglycerin has been proven effective in the acute control of variceal hemorrhage. Somatostatin is more effective in the control of active bleeding when compared to vasopressin, glypressin, endoscopic sclerotherapy or balloon tamponade. Octreotide has comparable outcomes to vasopressin, terlipressin or endoscopic sclerotherapy. **Liver transplantation** should be considered as an alternative for patients with bleeding varices from liver disease.

Another alternative treatment is provided by Transjugular intrahepatic portal-systemic shunting (TIPS). In TIPS, a catheter fitted with a stent, a wire mesh tube used to prop open a vein or artery, is inserted through a vein in the neck into the liver. Under x ray guidance, the stent is placed in an optimal position within the liver so as to allow blood to flow more easily through the portal vein. This treatment reduces the excess pressure in the

## QUESTIONS TO ASK THE DOCTOR

- What are esophageal varices?
- Are there alternatives to sclerotherapy?
- How do I prepare for surgery?
- What type of anesthesia will be used?
- How is the surgery performed?
- How long will I be in the hospital?
- How many sclerotherapy procedures do you perform in a year?

esophageal varices, and thus decreases the risk of recurrent bleeding.

## Sclerotherapy for varicose veins

### Definition

Sclerotherapy, which takes its name from a Greek word meaning “hardening,” is a method of treating enlarged veins by injecting an irritating chemical called a sclerosing agent into the vein. The chemical causes the vein to become inflamed, which leads to the formation of fibrous tissue and closing of the lumen, or central channel of the vein.

### Purpose

Sclerotherapy in the legs is performed for several reasons. It is most often done to improve the appearance of the legs, and is accomplished by closing down spider veins—small veins in the legs that have dilated under increased venous blood pressure. A spider vein is one type of telangiectasia, which is the medical term for a reddish-colored lesion produced by the permanent enlargement of the capillaries and other small blood vessels. The word telangiectasia comes from three Greek words that mean “end,” “blood vessel,” and “stretch out.” In a spider vein, also called a “sunburst varicosity,” there is a central reddish area that is visible to the eye because it lies close to the surface of the skin; smaller veins spread outward from it in the shape of a spider’s legs. Spider veins may also appear in two other common patterns—they may look like tiny tree branches or like extra-fine separate lines.

In addition to the cosmetic purposes sclerotherapy serves, it is also performed to treat the soreness, aching, muscle fatigue, and leg cramps that often accompany small- or middle-sized varicose veins in the legs. It is not, however, used by itself to treat large varicose veins.

Because sclerotherapy is usually considered a cosmetic procedure, it is usually not covered by health insurance. People who are being treated for cramps and discomfort in their legs, however, should ask their insurance companies whether they are covered for sclerotherapy. Sclerotherapy costs usually reflect the number of syringes of sclerosant required; the average cost of each syringe is \$225. Many procedures will require the use of two syringes of sclerosant. The average cost is \$326.

Sclerotherapy as a general treatment modality is also performed to treat hemorrhoids (swollen veins) in the esophagus.

### Demographics

The American College of Phlebology (ACP), a group of dermatologists, plastic surgeons, gynecologists, and general surgeons with special training in the treatment of venous disorders, comments that about 60% of all people in the United States suffer from spider veins or varicose veins. Women are more commonly affected than men, with about half of all women experiencing some type of vein disorder. The American Society of Plastic Surgeons (ASPS) estimates that more than 40% of women over 50 in the United States have spider veins.

Women are more likely to develop spider veins than men, but the incidence among both sexes increases with age. The results of a recent survey of middle-aged and elderly people in San Diego, California, show that 80% of the women and 50% of the men had spider veins. Men are less likely to seek treatment for spider veins for cosmetic reasons, however, because the discoloration caused by spider veins is often covered by leg hair. On the other hand, men who are bothered by aching, burning sensations or leg cramps can benefit from sclerotherapy.

According to the ASPS, there were 559,285 sclerotherapy procedures performed in the United States in 2006. Most people who are treated with sclerotherapy are between the ages of 30 and 60.

Spider veins are most noticeable and common in Caucasians. Hispanics are less likely than Caucasians but more likely than either African or Asian Americans to develop spider veins.

### Description

#### *Causes of spider veins*

To understand how sclerotherapy works, it is helpful to begin with a brief description of the venous system in the human body. The venous part of the circulatory system returns blood to the heart to be pumped to the lungs for oxygenation. This is in contrast to the arterial system, which carries oxygenated blood away from the heart to be distributed throughout the body. The smallest parts of the venous system are the capillaries, which feed into larger superficial veins. All superficial veins lie between the skin and a layer of fibrous connective tissue called fascia, which covers and supports the muscles and the internal organs. The deeper veins of the body lie within the muscle fascia. This distinction helps to explain why superficial veins can be treated by sclerotherapy without damage to the larger veins.

## Sclerotherapy for varicose veins

During sclerotherapy for the treatment of varicose veins, the doctor injects a chemical solution directly into the vein (A and B). The needle travels up the vein, and as it is pulled back, the chemical is released, causing the vein to form fibrous tissue that collapses the inside of it (C). (Illustration by GGS Information Services. Cengage Learning, Gale.)

Veins contain one-way valves that push blood inward and upward toward the heart when they are functioning normally. The blood pressure in the superficial veins is usually low, but if it rises and remains at a higher level over a period of time, the valves in the veins begin to fail and the veins dilate, or expand. Veins that are not functioning properly are said to be “incompetent.” As the veins expand, they become more noticeable because they lie closer to the

surface of the skin, forming the typical patterns seen in spider veins.

Some people are at greater risk for developing spider veins. These risk factors include:

- Sex. Females in any age group are more likely than males to develop spider veins.
- Genetic factors. Some people have veins with abnormally weak walls or valves. They may develop spider

## KEY TERMS

**Arteriole**—A very small branch of an artery, usually close to a capillary network.

**Edema**—The presence of abnormally large amounts of fluid in the soft tissues of the body.

**Electrodesiccation**—A method of treating spider veins or drying up tissue by passing a small electric current through a fine needle into the affected area.

**Hemosiderin**—A form of iron that is stored inside tissue cells. The brownish discoloration of skin that sometimes occurs after sclerotherapy is caused by hemosiderin.

**Hirsutism**—Abnormal hair growth on the part of the body treated by sclerotherapy. It is also called hypertrichosis.

**Incompetent**—In a medical context, insufficient. An incompetent vein is one that is not performing its function of carrying blood back to the heart.

**Lumen**—The channel or cavity inside a tube or hollow organ of the body.

**Palpation**—Examining by touch as part of the process of physical diagnosis.

**Percussion**—Thumping or tapping a part of the body with the fingers for diagnostic purposes.

**Phlebology**—The study of veins, their disorders, and their treatments. A phlebologist is a doctor who specializes in treating spider veins, varicose veins, and associated disorders.

**Sclerose**—To harden or undergo hardening. Sclerosing agents are chemicals that are used in sclerotherapy to cause swollen veins to fill with fibrous tissue and close down.

**Spider nevus (plural, nevi)**—A reddish lesion that consists of a central arteriole with smaller branches radiating outward from it. Spider nevi are also called spider angiomas; they are most common in small children and pregnant women.

**Spider veins**—Telangiectasias that appear on the surface of the legs, characterized by a reddish central point with smaller veins branching out from it like the legs of a spider.

**Telangiectasia**—The medical term for the visible discolorations produced by permanently swollen capillaries and smaller veins.

**Varicose**—Abnormally enlarged and distended.

veins even without a rise in blood pressure in the superficial veins.

- **Pregnancy.** A woman's total blood volume increases during pregnancy, which increases the blood pressure in the venous system. In addition, the hormonal changes of pregnancy cause the walls and valves in the veins to soften.
- **Using birth control pills.**
- **Obesity.** Excess body weight increases pressure on the veins.
- **Occupational factors.** People whose jobs require standing or sitting for long periods of time without the opportunity to walk or move around are more likely to develop spider veins than people whose jobs allow more movement.
- **Trauma.** Falls, deep bruises, cuts, or surgical incisions may lead to the formation of spider veins in or near the affected area.

As of 2008, there is no known method to prevent the formation of spider veins.

### *Sclerotherapy procedures*

In typical outpatient sclerotherapy treatment, the patient changes into a pair of shorts at the doctor's office and lies on an examination table. After cleansing the skin surface with an antiseptic, the doctor injects a sclerosing agent into the veins. This agent is eliminated when the skin is stretched tightly over the area with the other hand. The doctor first injects the larger veins in each area of the leg, then the smaller ones. In most cases, one injection is needed for every inch of spider vein; a typical treatment session will require five to 40 separate injections. No anesthetic is needed for sclerotherapy, although the patient may feel a mild stinging or burning sensation at the injection site.

The liquid sclerosing agents that are used most often to treat spider veins are polidocanol (aethoxysklerol), sodium tetradecyl sulfate, and saline solution at 11.7% concentration. Some practitioners prefer to use saline because it does not cause allergic reactions. The usual practice is to use the lowest concentration of the chemical that is still effective in closing the veins.

A newer type of sclerosing agent is a foam instead of a liquid chemical that is injected into the veins. The foam has several advantages: It makes better contact with the wall of the vein than a liquid sclerosing agent; it allows the use of smaller amounts of chemical; and its movement in the vein can be monitored on an **ultrasound** screen. Sclerosing foam has been shown to have a high success rate with a lower cost, and causes fewer major complications.

After all the veins in a specific area of the leg have been injected, the doctor covers the area with a cotton ball or pad and compression tape. The patient may be asked to wait in the office for 20–30 minutes after the first treatment session to ensure that there is no hypersensitivity to the sclerosing chemicals. Most sclerotherapy treatment sessions are short, lasting from 15 to 45 minutes.

It is not unusual for patients to need a second treatment to completely eliminate the spider veins; however, it is necessary to wait four to six weeks between procedures.

## Diagnosis/Preparation

### *Diagnosis*

The most important aspect of diagnosis prior to undergoing sclerotherapy is distinguishing between telangiectasias and large varicose veins, and telangiectasias and spider nevi. Because sclerotherapy is intended to treat only small superficial veins, the doctor must confirm that the patient does not have a more serious venous disorder.

Spider nevi, which are also called “spider angiomas,” are small, benign reddish lesions that consist of a central arteriole, which is a very small branch of an artery with smaller vessels radiating from it. Although the names are similar, spider nevi occur in the part of the circulatory system that carries blood (away) from the heart, whereas spider veins occur in the venous system that returns blood to the heart. To distinguish between the two, the doctor will press gently on the spot in the center of the network. A spider nevus will blanch, or lose its reddish color, when the central arteriole is compressed. When the doctor releases the pressure, the color will return. Spider veins are not affected by compression in this way. In addition, spider nevi occur most frequently in children and pregnant women, rather than in older adults. They are treated by laser therapy or electrodesiccation, rather than by sclerotherapy.

After taking the patient’s medical history, the doctor examines the patient from the waist down,

both to note the location of spider veins and to palpate (touch with gentle pressure) them for signs of other venous disorders. Ideally, the examiner will have a small, raised platform for the patient to stand on during the examination. The doctor will ask the patient to turn slowly while standing, and will be looking for scars or other signs of trauma, bulges in the skin, areas of discolored skin, or other indications of chronic venous insufficiency. While palpating the legs, the doctor will note areas of unusual warmth or soreness, cysts, and edema (swelling of the soft tissues due to fluid retention). Next, the doctor will percuss certain parts of the legs where the larger veins lie closer to the surface. By gently tapping or thumping on the skin over these areas, the doctor can feel fluid waves in the veins and determine whether further testing for venous insufficiency is required. If the patient has problems related to large varicose veins, these must be treated before sclerotherapy can be performed to eliminate spider veins.

Some conditions and disorders are considered contraindications for sclerotherapy:

- Pregnancy and lactation. Pregnant women are advised to postpone sclerotherapy until at least three months after the baby is born, because some spider veins will fade by themselves after delivery. Nursing mothers should postpone sclerotherapy until the baby is weaned because it is not yet known whether the chemicals used in sclerotherapy may affect the mother’s milk.
- Diabetes.
- A history of AIDS, hepatitis, syphilis, or other diseases that are carried in the blood.
- Heart conditions.
- High blood pressure, blood clotting disorders, and other disorders of the circulatory system.

### *Preparation*

Patients are asked to discontinue **aspirin** or aspirin-related products for a week before sclerotherapy. Further, they are told not to apply any moisturizers, creams, tanning lotions, or sunblock to the legs on the day of the procedure. Patients should bring a pair of shorts to wear during the procedure, as well as compression stockings and a pair of slacks or a long skirt to cover the legs afterwards.

Most practitioners will take photographs of the patient’s legs before sclerotherapy to evaluate the effectiveness of treatment. In addition, some insurance companies request pretreatment photographs for documentation purposes.

## Aftercare

Aftercare following sclerotherapy includes wearing medical compression stockings that apply either 20–30 mmHg or 30–40 mmHg of pressure for at least seven to 10 days (preferably four to six weeks) after the procedure. Wearing compression stockings minimizes the risk of edema, discoloration, and pain. Fashion support stockings are a less acceptable alternative because they do not apply enough pressure to the legs.

The surgical tape and cotton balls used during the procedure should be left in place for 48 hours after the patient returns home.

Patients are encouraged to walk, ride a bicycle, or participate in other low-impact forms of **exercise** (examples: yoga and tai chi) to prevent the formation of blood clots in the deep veins of the legs. They should, however, avoid prolonged periods of standing or sitting, and high-impact activities, such as jogging.

## Risks

Cosmetically, the chief risk of sclerotherapy is that new spider veins may develop after the procedure. New spider veins are dilated blood vessels that can form when some of the venous blood forms new pathways back to the larger veins; they are not the original blood vessels that were sclerosed. Some patients may develop telangiectatic matting, which is a network of new spider veins that surface around the treated area. Telangiectatic matting usually clears up by itself within three to 12 months after sclerotherapy, but it can also be treated with further sclerosing injections.

Other risks of sclerotherapy include:

- Venous thrombosis. A potentially serious complication, thrombosis refers to the formation of blood clots in the veins.
- Severe inflammation.
- Pain after the procedure lasting several hours or days. This discomfort can be eased by wearing medical compression stockings and by walking briskly.
- Allergic reactions to the sclerosing solution or foam.
- Permanent scarring.
- Loss of feeling resulting from damage to the nerves in the treated area.
- Edema (swelling) of the foot or ankle. This problem is most likely to occur when the foot or ankle is treated for spider veins. The edema usually resolves within a few days or weeks.
- Brownish spots or discoloration in the skin around the treated area. These changes in skin color are caused by deposits of hemosiderin, which is a form

of iron that is stored within tissue cells. The spots usually fade after several months.

- Ulceration of the skin. This complication may result from reactive spasms of the blood vessels, the use of overly strong sclerosing solutions, or poor technique in administering sclerotherapy. It can be treated by diluting the sclerosing chemical with normal saline solution.
- Hirsutism. Hirsutism is the abnormal growth of hair on the area treated by sclerotherapy. It usually develops several months after treatment and goes away on its own. It is also known as hypertrichosis.

## Normal results

Normal results of sclerotherapy include improvement in the external appearance of the legs and relief of aching or cramping sensations associated with spider veins. It is common for complete elimination of spider veins to require three to four sclerotherapy treatments.

## Morbidity and mortality rates

Mortality associated with sclerotherapy for spider veins is almost 0% when the procedure is performed by a competent doctor. The rates of other complications vary somewhat, but have been reported as falling within the following ranges:

- Hemosiderin discoloration: 10%–80% of patients, with fewer than 1% of cases lasting longer than a year.
- Telangiectatic matting: 5%–75% of patients.
- Deep venous thrombosis: Fewer than 1%.
- Mild aching or pain: 35%–55%.
- Skin ulceration: About 4%.

## Alternatives

### Conservative treatments

Patients who are experiencing some discomfort from spider veins may be helped by any or several of the following approaches:

- Exercise. Walking or other forms of exercise that activate the muscles in the lower legs can relieve aching and cramping because these muscles keep the blood moving through the leg veins. One exercise that is often recommended is repeated flexing of the ankle joint. By flexing the ankles five to 10 times every few minutes and walking around for one to two minutes every half hour throughout the day, the patient can prevent the venous congestion that results from sitting or standing in one position for hours at a time.

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

Sclerotherapy is usually performed by general surgeons, dermatologists, or plastic surgeons, but it can also be done by family physicians or naturopaths who have been trained to do it. The American College of Phlebology holds workshops and intensive practical courses for interested practitioners. The ACP can be contacted for a list of members in each state.

Sclerotherapy is done as an outpatient procedure, most often in the doctor's office or in a plastic surgery clinic.

- Avoiding high-heeled shoes. Shoes with high heels do not allow the ankle to flex fully when the patient is walking. This limitation of the range of motion of the ankle joint makes it more difficult for the leg muscles to contract and force venous blood upwards toward the heart.
- Elevating the legs for 15–30 minutes once or twice a day. This change of position is frequently recommended for reducing edema of the feet and ankles.
- Wearing compression hosiery. Compression benefits the leg veins by reducing inflammation as well as improving venous outflow. Most manufacturers of medical compression stockings now offer some relatively sheer hosiery that is both attractive and that offers support.
- Medications. Drugs that have been used to treat the discomfort associated with spider veins include non-steroidal anti-inflammatory drugs (NSAIDs) and preparations of vitamins C and E. One prescription medication that is sometimes given to treat circulatory problems in the legs and feet is pentoxifylline, which improves blood flow in the smaller capillaries. Pentoxifylline is sold under the brand name Trendar.

If appearance is the patient's primary concern, spider veins on the legs can often be covered with specially formulated cosmetics that come in a wide variety of skin tones. Some of these preparations are available in waterproof formulations for use during swimming and other athletic activities.

### *Electrodesiccation, laser therapy, and pulsed light therapy*

Electrodesiccation is a treatment modality whereby the doctor seals off the small blood vessels that cause

## QUESTIONS TO ASK THE DOCTOR

- How likely am I to develop new spider veins in the treated areas?
- Do you use the newer sclerosing foams when you administer sclerotherapy?
- What technique(s) do you prefer to use for sclerotherapy and why?

spider veins by passing a weak electric current through a fine needle to the walls of the veins. Electrodesiccation seems to be more effective in treating spider veins in the face than in treating those in the legs; it tends to leave pitted white scars when used to treat spider veins in the legs or feet.

Laser therapy, like electrodesiccation, works better in treating facial spider veins. The sharply focused beam of intense light emitted by the laser heats the blood vessel, causing the blood in it to coagulate and close the vein. Various lasers have been used to treat spider veins, including argon, KTP 532nm, and alexandrite lasers. The choice of light wavelength and pulse duration are based on the size of the vein to be treated. Argon lasers, however, have been found to increase the patient's risk of developing hemosiderin discoloration when used on the legs. The KTP 532nm laser gives better results in treating leg spider veins, but is still not as effective as sclerotherapy.

Intense pulsed light (IPL) systems differ from lasers because the light emitted is noncoherent and not monochromatic. The IPL systems enable doctors to use a wider range of light wavelengths and pulse frequencies when treating spider veins and other skin problems, such as pigmented birthmarks. This flexibility, however, requires considerable skill and experience on the part of the doctor to remove spider veins without damaging the surrounding skin.

### *Complementary and alternative (CAM) treatments*

According to Dr. Kenneth Pelletier, the former director of the program in complementary and alternative treatments at Stanford University School of Medicine, California, horse chestnut extract is as safe and effective as compression stockings when used as a conservative treatment for spider veins. Horse chestnut (*Aesculus hippocastanum*) has been used in Europe for some years to treat circulatory problems in the legs; most recent research has been conducted in

Great Britain and Germany. The usual dosage is 75 mg twice a day, at meals. The most common side effect of oral preparations of horse chestnut is occasional indigestion in some patients.

## Scopolamine patch

### Definition

A scopolamine patch (Transdermal Scop or Transderm-V) is an adhesive medication patch that is applied to the skin behind the ear the night before surgery or a caesarean section. The patch is treated with the belladonna alkaloid scopolamine, an anticholinergic drug that is a central nervous system depressant and an antiemetic.

### Purpose

Scopolamine patches are prescribed to reduce post-operative nausea and vomiting (PONV) associated with anesthesia and surgery. Scopolamine also has a mild analgesic and sedative effect, which adds to its therapeutic value for some surgical patients. In addition to PONV, scopolamine patches are also used for the treatment of motion sickness.

### Demographics

Elderly patients may be more sensitive to scopolamine treatment and its use should be prescribed with caution in this group. The safety of scopolamine patches has not been determined in children; according to the Food and Drug Administration (FDA), the patch should not be used in children.

## KEY TERMS

**Anticholinergic**—Drugs that block the action of acetylcholine, a neurotransmitter, consequently impairing the parasympathetic (involuntary) nervous system. Anticholinergic drugs inhibit secretion of bodily fluids (i.e., saliva, perspiration, stomach acid).

**Antiemetic**—A drug that prevents emesis, or vomiting.

## Description

A potent drug derived from an alkaloid of belladonna (*Atropa belladonna*; common name deadly nightshade), scopolamine works by depressing the action of the nerve fibers near the ear and the vomiting center of the brain and central nervous system (CNS). The patch itself is designed with special layered materials that slowly release a small dose of the drug transdermally (through the skin) over a period of several days.

Patients who are instructed to apply their patch at home should wash their hands thoroughly both before and after the procedure. Scopolamine can be spread to the eyes by hand, which can cause blurred vision and pupil dilation. Patches should never be cut into pieces, as cutting destroys the time-release mechanism of the drug. The directions for use for the patch should be read thoroughly before application, and specific physician instructions should also be followed. The drug will start to work approximately four hours after the patch is applied.

## Diagnosis/Preparation

The dime-sized scopolamine patch is applied just behind either the left or right ear. The area should be clean and hairless prior to the application, which should occur the evening before a scheduled surgery. For women who are prescribed a scopolamine patch to reduce nausea and vomiting related to a **cesarean section**, the patch should be applied just one hour before the procedure to minimize the baby's exposure to the drug. Scopolamine does cross the placental barrier, but as of early 2003, clinical studies have not shown any negative affects on newborn babies of mothers who used the drug in a caesarean delivery.

Patients with a history of glaucoma, prostate enlargement, kidney or liver problems, bladder obstruction, gastrointestinal obstruction, or contact dermatitis (allergic skin rash) in response to topical drugs may not be suitable candidates for scopolamine patch therapy. A

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

When used for surgical implications, a scopolamine patch may be ordered by a physician, surgeon, or anesthesiologist, typically in a hospital setting or an ambulatory surgery center. The patch may be applied at home by the patient, or by a nurse or physician's assistant as part of preoperative preparation.

physician or anesthesiologist should take a full medical history before prescribing scopolamine to determine if the medication is appropriate.

## Aftercare

Patients who receive a scopolamine patch should not drive or operate heavy machinery until the therapy is complete. Patch therapy generally lasts about three days. Patches should be disposed of according to the manufacturer's directions in a secure place to ensure that small children or pets do not get access to them. If PONV has not resolved after patch therapy has ended, patients should talk to their doctor about their treatment options.

## Risks

Possible complications or side effects from transdermal scopolamine include but are not limited to: short-term memory loss, fatigue, confusion, hallucinations, difficulty urinating, and changes in heart rate. The drug can trigger seizures and psychotic delusions in patients with a history of these problems. Dizziness, nausea, headache, and hypotension (low blood pressure) have also been reported in some patients upon discontinuation of scopolamine patch therapy.

Patients who experience eye pain with redness and possible blurred vision should remove the patch immediately and call their doctor, since the symptoms could be signs of a rare but possible side effect of scopolamine called narrow-angle glaucoma. Blurriness with or without pupil dilation is also a potential but generally harmless side effect of the drug.

The FDA recommends that patients who are scheduled for a **magnetic resonance imaging (MRI)** scan remove the patch before the scan, as the patch's backing contains aluminum. The aluminum absorbs energy and heats up during the scan, which may cause a mild burn of the skin beneath the patch.

## QUESTIONS TO ASK THE DOCTOR

When preparing to receive scopolamine transdermal therapy, you might ask your doctor:

- When and how do I apply the patch?
- What should I do if the patch becomes loose or falls off?
- When can I remove or replace the patch?
- Are there any warning symptoms that should signal me to remove the patch?

### Normal results

When scopolamine patch therapy works, it reduces or eliminates post-surgical nausea and vomiting. Two-thirds of patients experience dry mouth, the most common side effect of the drug.

### Alternatives

Intravenous or intramuscular injection of scopolamine may be used as alternatives to patch therapy for some patients. Other antiemetics that may be prescribed for PONV include anticholinergic drugs, dopaminergic drugs (i.e., promethazine, droperidol), antihistamines (i.e., diphenhydramine), and the serotonin receptor antagonists (i.e., ondansetron, granisetron, tropisetron, dolasetron). **Corticosteroids** may also be recommended for PONV in some patients.

## Second-look surgery

### Definition

Second-look surgery is performed after a procedure or course of treatment to determine if the patient is free of disease. If disease is found, additional procedures may or may not be performed at the time of second-look surgery.

### Purpose

Second-look surgery may be performed under numerous circumstances on patients with various medical conditions.

### Cancer

A second-look procedure is sometimes performed to determine if a cancer patient has responded successfully to a particular treatment. Examples of cancers that are assessed during second-look surgery are ovarian cancer and colorectal cancer. In many cases, before a round of chemotherapy and/or radiation therapy is started, a patient will undergo a surgical procedure called cytoreduction to reduce the size of a tumor. This debulking increases the sensitivity of the tumor and decreases the number of necessary treatment cycles. Following cytoreduction and chemotherapy, a second-look procedure may be necessary to determine if the area is cancer-free.

An advantage to second-look surgery following cancer treatment is that if cancer is found, it may be removed during the procedure in some patients. In other cases, if a tumor cannot be entirely removed, the surgeon can debulk the tumor and improve the patient's chances of responding to another cycle of chemotherapy. However, second-look surgery cannot definitively prove that a patient is free of cancer; some microscopic cancer cells can persist and begin to grow in other areas of the body. Even if no cancer is found during second-look surgery, the rate of cancer relapse is approximately 25%.

## KEY TERMS

**Adhesion**—A band of internal scar tissue that develops after injury or surgery.

**Anastomosis (plural, anastomoses)**—The surgical connection of two structures, such as blood vessels or sections of the intestine.

**Cholesteatoma**—A destructive and expanding sac that develops in the middle ear or mastoid process.

**Debulking**—The removal of part of a malignant tumor in order to make the remainder more sensitive to radiation or chemotherapy.

**Endometriosis**—The growth of tissue like the lining of a woman's uterus (endometrium) outside the uterus in other parts of the body.

**Endoscopy**—A surgical technique that uses an endoscope (a thin, lighted, telescope-like instrument) to visualize structures inside the human body.

**Infertility**—The inability to become pregnant or carry a pregnancy to term.

**Ischemia**—Inadequate blood supply to an organ or area of tissue due to obstruction of a blood vessel.

**Kidney stones**—Small solid masses that form in the kidney.

### *Pelvic disease*

Second-look surgery may benefit patients suffering from a number of different conditions that affect the pelvic organs. Endometriosis is a condition in which the tissue that lines the uterus grows elsewhere in the body, usually in the abdominal cavity, leading to pain and scarring. Endometrial growths may be surgically removed or treated with medications. A second-look procedure may be performed following the initial surgery or course of medication to determine if treatment was successful in reducing the number of growths. Additional growths may be removed at this time.

Second-look surgery may also be performed following the surgical removal of adhesions (bands of scar tissue that form in the abdomen following surgery or injury) or uterine fibroids (noncancerous growths of the uterus). If the results are positive, an additional procedure may be performed to remove the adhesions or growths. Patients undergoing treatment for infertility may benefit from a second-look procedure to determine if the cause of infertility has been cured before ceasing therapy.

### *Abdominal disease*

In patients suffering from bleeding from the gastrointestinal (GI) tract, recurrence of bleeding after attempted treatment remains a significant risk; approximately 10–25% of cases do not respond to initial treatment. Second-look surgery following treatment for GI bleeding may be beneficial in determining if bleeding has recurred and treating the cause of the bleeding before it becomes more extensive.

Patients suffering from a partial or complete blockage of the intestine are at risk of developing bowel ischemia (**death** of intestinal tissue due to a lack of oxygen). Initial surgery is most often necessary to remove the diseased segment of bowel; a second-look procedure is commonly performed to ensure that only healthy tissue remains and that the new intestinal connection (called an anastomosis) is healing properly.

### *Other conditions*

A variety of other conditions can be assessed with second-look surgery. Patients who have undergone surgical repair of torn muscles in the knee might undergo a procedure called second-look arthroscopy to assess whether the repair is healing. A physician may use second-look mastoidoscopy to visualize the middle ear after removal of a cholesteatoma (a benign but destructive growth in the middle ear). A second endoscopic procedure may be performed on a patient who underwent endoscopic treatment for sinusitis (chronic infection of the sinuses) to evaluate the surgical site and remove debris.

## Description

Second-look surgery may be performed within hours, days, weeks, or months of the initial procedure or treatment. This time interval depends on the patient's condition and the type of procedure.

### *Laparotomy*

A laparotomy is a large incision through the abdominal wall to visualize the structures inside the abdominal cavity. After placing the patient under **general anesthesia**, the surgeon first makes a large incision through the skin, then through each layer under the skin in the region that the surgeon wishes to explore. The area will be assessed for evidence of remaining disease. For example, in the case of second-look laparotomy following treatment for endometriosis, the abdominal organs will be examined for evidence of endometrial growths. In the case of cancer, a “washing” of the abdominal cavity may be performed; sterile fluid is instilled into the abdominal cavity and washed

around the organs, then extracted with a syringe. The fluid is then analyzed for the presence of cancerous cells. Biopsies may also be taken of various abdominal tissues and analyzed.

If the surgeon discovers evidence of disease or a failed surgical repair, additional procedures may be performed to remove the disease or repair the dysfunction. For example, if adhesions are encountered during a second-look procedure on an infertile female patient, the surgeon may remove the adhesions at that time. Upon completion of the procedure, the incision is closed.

### Laparoscopy

**Laparoscopy** is a surgical technique that permits a view of the internal abdominal organs without an extensive surgical incision. During laparoscopy, a thin lighted tube called a laparoscope is inserted into the abdominal cavity through a tiny incision. Images taken by the laparoscope are seen on a video monitor connected to the scope. The surgeon may then examine the abdominal cavity, albeit with a more limited operative view than with laparotomy. Procedures such as the removal of growths or repair of deformities can be performed by instruments inserted through other small incisions in the abdominal wall. After the procedure is completed, any incisions are closed with **stitches**.

### Other procedures

Depending on the area of the body in question, other procedures may be used to perform second-look surgery. These include:

- **Arthroscopy.** Arthroscopy uses a thin endoscope to visualize the inner space of a joint such as the knee or elbow. Second-look arthroscopy may be used to determine if previous surgery on the joint is healing properly.
- **Percutaneous nephrolithotomy (PNL).** This minimally invasive procedure is used to remove kidney stones. Second-look PNL may be used to remove fragments of stones that could not be removed during the initial procedure.
- **Hysteroscopy.** A hysteroscope is an instrument used to visualize and perform procedures on the inner cavity of the uterus. Second-look hysteroscopy may be used after surgery or medical treatment to treat adhesions or benign growths in the uterus to determine if they have been effectively removed.
- **Mastoidectomy.** This surgical procedure is used to treat cholesteatoma; a second-look procedure is

generally performed to ensure that the entire cholesteatoma was removed during the initial procedure.

## Second opinion

### Definition

A second opinion is the result of seeking an evaluation by another doctor or surgeon to confirm the diagnosis and treatment plan of a primary physician, or to offer an alternative diagnosis and/or treatment approach.

### Purpose

Getting a second surgical opinion can fill an important emotional need as well as establishing medical needs and treatment goals. When a second opinion confirms initial findings, it can provide reassurance and feelings of acceptance for the patient, and may reduce anxiety and uncertainty.

From a cost-effectiveness point of view, second opinions can save health insurance providers money by establishing the certainty of a clinical need (or lack of need) for surgery, particularly when the diagnosis is life-threatening.

Patients with a diagnosis of cancer may also benefit from a second-opinion pathology review of their biopsy material. A Johns Hopkins study reported that 1.4% of patients scheduled for cancer-related surgery at their facility were found to have been misdiagnosed when their tissue samples were reevaluated by a second pathologist. Similarly, a study published in the *Annals of Surgical Oncology* in 2002 found that a pathological second opinion of breast cancers changed the initial diagnosis, prognosis, or treatment approach in 80% of the 340 study subjects.

Several clinical research studies, however, have found that patients often seek second opinions not necessarily because they doubt the diagnosis or recommendations of their first provider, but because they were dissatisfied with either the amount of information given to them or the style of communication of their doctor. A 2002 Northwestern University study found that only 46% of patients coming into a breast cancer treatment center for a second opinion had been offered a complete discussion of treatment options during their initial consultation.

### Description

Doctors often have differing viewpoints as to how a particular medical problem should be managed, whether through surgery or less-invasive treatment means. One surgeon may prefer to take a “watchful waiting” approach before recommending surgery, while

## KEY TERMS

**Informed consent**—Providing a patient with complete, objective information on the risks, benefits, and potential and probable outcomes of different surgical or therapeutic options so that they may make an informed decision or consent to treatment.

**Pathologist**—A physician with specialized training in recognizing and identifying diseases through the analysis of abnormal bodily tissues.

**Postoperative care**—Medical care and support required after surgery to promote healing and recovery.

**Watchful waiting**—Monitoring a patient’s disease state carefully to see if the condition worsens before trying surgery or another therapy. This term is often associated with prostate cancer.

another may believe in performing surgery as soon as possible to avoid later complications. In some cases, several surgical techniques may be viable options for a patient. Medicine is not as black-and-white as many patients are led to believe, and physicians are not infallible. For these reasons, and because surgery is a major procedure with associated risks that should not be taken lightly, second opinions are an important part of the process of **informed consent** and decision-making.

Although a physician may strive to be objective, personal views and subjective experiences can influence their treatment recommendations. In addition, both the education and experience of a doctor in a given medical area can also influence the advice they offer a patient. For these reasons, seeking a second opinion from another physician and/or surgeon can be invaluable in making a decision on a course of treatment.

Second opinions are most frequently sought in cases of elective (nonemergency) surgery, when the patient has time to consider options and make a more informed choice about his or her course of treatment. While a second surgical opinion may be requested in some cases of **emergency surgery**, they are not as common, simply because of the logistical limitations involved with getting a qualified second opinion if a patient requires immediate care.

In some cases, a doctor or surgeon may encourage seeking a second opinion, particularly when the preferred course of treatment is not clear-cut or another surgeon with advanced training or expertise may

provide more insights into surgical options. A doctor or surgeon may also recommend seeking a second opinion when the patient is suffering from multiple medical disorders.

Patients should remember that it is their right to seek a second opinion before committing to surgery or another treatment plan. Embarrassment or fear of disapproval from a primary care provider should not be a barrier to getting a second opinion. A competent physician will not consider the decision to seek a second opinion an insult to their ability or experience. Instead, they will consider the patient an informed individual who is proactive and responsible for his or her own health care.

Patients seeking a second-opinion consultation may ask the provider questions similar to those they asked their primary provider. Questions may include:

- Are there other options besides surgery?
- What are the risks and benefits of each treatment option?
- How might each possible treatment impact quality-of-life for the patient?
- What kind of success rate is associated with surgery and other potential therapies?
- How is the surgery performed?
- Is surgery a permanent, long-term, or temporary solution to the condition?
- What type of anesthesia will be used?
- If surgery is chosen by the patient, how soon must it be done?
- What type of aftercare and recovery time is required once the surgery is complete?
- How much pain is to be expected postoperatively, and how is it typically treated?
- What are the costs involved with surgery and other treatment options, including postoperative care?

Providing the second surgeon with appropriate background information is important, but so is refraining from detailed descriptions of what the first provider did or did not recommend before the consultation begins. Patients should allow the surgeon to draw objective conclusions based on the medical history and diagnostic data before them. If the second opinion differs from the first provider's opinion, and the patient feels comfortable doing so, he or she might then offer information on the first provider's recommendations to get further feedback and input for a final decision.

## Preparation

Before seeking a second opinion, patients should contact their health insurance provider to find out if the service is covered. Some insurance companies may request that a second opinion be sought before major **elective surgery**, and may reserve the right to designate a physician or surgeon to provide the patient evaluation. As of early 2008, **Medicare Part B** covered 80% of costs for surgical second opinions after deductible, and 80% for a third opinion if the first two opinions are contradictory. Other Medicare programs may cover second opinions as well; patients should check with their Medicare carrier for details.

There are several ways to find an appropriate health care professional to provide a second opinion. Patients can:

- Ask friends and family for references.
- Ask their primary care physician or another trusted health care provider for a referral.
- Contact an appropriate specialty medical organization (e.g., American College of Surgeons) for a referral.
- Call their local medical licensing board.
- Check with their insurance provider or Medicare carrier.
- Cancer patients can consult a list of multidisciplinary institutions that will provide a second opinion on request. The list is available at < <http://www.blochcancer.org/>>.

When seeking a second surgical opinion, patients should find a surgeon who is board certified in the appropriate specialty by an organization that is part of the American Board of Medical Specialties (ABMS). For example, surgery of the urinary tract may be performed by a provider who is board certified by the American Board of Urology and/or the American Board of Surgery (ABS), two member organizations of the ABMS. Diplomates of ABMS member boards are surgeons who have passed rigorous written and oral testing on these specialties and have met specific accredited educational and residency requirements. In some cases, surgeons may also be certified in subspecialties within a discipline (for example, a vascular surgeon may be board certified by the **vascular surgery** board of the ABS). The ABMS provides a verification service for patients to check on the certification status of their provider.

In addition, the surgeon may also be a Fellow of the American College of Surgery (ACS), as indicated by the designation F.A.C.S. after their name. This indicates that he or she has met standards of clinical

experience, education, ethical conduct, and professional expertise as prescribed by the ACS.

Once a second health care provider is selected, patients should speak with their primary doctor about providing the appropriate medical history, test results, and other pertinent information to the physician who will give the second opinion. The patient may have to sign an information release form to allow the files to be sent. If x rays, **magnetic resonance imaging (MRI)**, or other radiological testing was performed, the second physician may request to see the original films, rather than the radiologist's report of the results, in order to interpret them objectively. In some cases, the office of the surgeon giving the second opinion can arrange to have these materials transferred with a patient's written approval. Patients should call ahead to ensure that all needed materials arrive at the second provider's office before the appointment, to give that physician adequate time to review them and to avoid potentially costly repeat testing.

### Normal results

Second opinions that agree with the first provider's conclusions may help ease the patient's mind and provide a clearer picture of the necessary course of treatment or surgery. However, if a patient still feels uncomfortable with the treatment plan outlined by the first and second physicians, or strongly disagrees with their conclusions, a third opinion from another provider is an option.

In cases in which the second provider disagrees with the first provider on diagnosis and/or treatment, the patient has harder choices to face. Again, a third evaluation may be in order from yet another physician, and some insurance companies may actually require this step in cases of conflicting opinions. If a patient is very comfortable with and confident in their primary care provider, they may wish to revisit them to review the second opinion.

In all cases, a patient should remember that their personal preferences, beliefs, and lifestyle considerations must also be considered in their final decision on surgery or treatment, as they are the ones who will live with the results.

## Sedation, conscious

### Definition

Conscious sedation, produced by the administration of certain medications, is an altered level of consciousness that still allows a patient to respond to physical stimulation and verbal commands, and to maintain an unassisted airway.

### Purpose

The purpose of conscious sedation is to produce a state of relaxation and/or pain relief by using benzodiazepine-type and narcotic medications to facilitate a procedure such as a biopsy, radiologic imaging study, endoscopic procedure, radiation therapy, or **bone marrow aspiration**.

### Description

Sedation is used inside or outside the **operating room**. Outside the operating suite, medical specialists use sedation to calm and relax their patients.

If the patient is to undergo a minor surgical procedure, screening and assessment of medical conditions that may interfere with conscious sedation must be explored. These potential risk factors include advanced age, history of adverse reactions to the proposed medications, and a past medical history of severe cardiopulmonary (heart/lung) disease. Other than those risk factors, contraindications for conscious sedation include; recent ingestion of large food or fluid volumes or a physical class IV or greater.

Once it has been established that the patient would be a good candidate for conscious sedation, just prior to the surgery or procedure, the patient will receive the sedating drug intravenously. A clip-like apparatus will be placed on the patient's finger to monitor oxygen intake during the sedation. This oxygen monitoring is called pulse oximetry and is a valuable, continuous monitor of patient oxygenation.

Dosing of medications that produce conscious sedation is individualized, and the medication is administered slowly to gauge a patient's response to the sedative. The two most common medications used to sedate patients for medical procedures are midazolam and fentanyl.

Fentanyl is a medication classified as an opioid narcotic analgesic (pain reliever) that is 50 to 100 times more potent than morphine. Given intravenously, the onset of action of fentanyl is almost immediate, and peak analgesia occurs within 10 to 15 minutes. A single dose of fentanyl given intravenously can produce good analgesia for only 20 to 45 minutes for most patients because the drug's distribution shifts from the brain (central nervous system) to peripheral tissues. The key to correct dosage is titration, or giving the medication in small amounts until the desired patient response is achieved.

Midazolam is a medication classified as a short-acting benzodiazepine (sedative) that depresses the central nervous system. Midazolam is ineffective for pain and has no analgesic effect during conscious sedation. The drug is a primary choice for conscious sedation because midazolam causes patients to have no recollection of the medical procedure. In general, midazolam has a fast-acting, short-lived sedative effect when given intravenously, achieving sedation within one to five minutes and peaking within 30 minutes. The effects of midazolam typically last one hour but may persist for six hours (including the amnestic effect). Patients who receive midazolam for conscious sedation should not be allowed to drive home after the procedure.

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

Conscious sedation is administered by medical or pediatric specialists performing a procedure that may be diagnostic and/or therapeutic. It may be used in a hospital, outpatient care facility, or doctor's office.

## Monitoring

Patient monitoring during conscious sedation must be performed by a trained and licensed health care professional. This clinician must not be involved in the procedure, but should have primary responsibility of monitoring and attending to the patient. Equipment must be in place and organized for monitoring the patient's blood pressure, pulse, respiratory rate, level of consciousness, and, most important, the oxygen saturation (the measure of oxygen perfusion inside the body) with a **pulse oximeter** (a machine that provides a continuous real-time recording of oxygenation). The oxygen saturation is the most sensitive parameter affected during increased levels of conscious sedation. **Vital signs** and other pertinent recordings must be monitored before the start of the administration of medications, and then at a minimum of every five minutes thereafter until the procedure is completed. After the procedure has been completed, monitoring should continue every 15 minutes for the first hour after the last dose of medication(s) was administered. After the first hour, monitoring can continue as needed. Children who receive sedative medication with a long half-life may require extended observation.

## Risks and risk management

The American Academy of Pediatrics (AAP) has established safe practice guidelines to manage conscious sedation without an anesthesiologist for minor procedures. These AAP criteria include (1) a full-time licensed clinician (nurse, physician, physician assistant, surgeon assistant, respiratory therapist) who is strictly and exclusively monitoring the patient's breathing, level of consciousness, vital signs, and airway; (2) standard procedures for monitoring vital signs; and (3) immediate availability (on site) of airway equipment, resuscitative medications, suction apparatus, and supplemental oxygen delivery systems.

## QUESTIONS TO ASK THE DOCTOR

When should I stop taking my regular medications? When should I begin them again?

What side effects can I expect after the procedure? Nausea? Dizziness? Drowsiness? Is there anything I can do to ward off these side effects?

What are the risks of this procedure?

Which sedative will you use?

What steps will you take if there are complications?

Will I feel any pain?

If adverse reactions occur while using fentanyl, the antidote is a drug called naloxone. It provides rapid reversal of fentanyl's narcotic effect. The incidence of oversedation or decreased respiration is low using fentanyl if the medication is carefully titrated.

## Sedimentation rate

### Definition

The sedimentation rate (or erythrocyte sedimentation rate) is a test that measures that degree of inflammation occurring in the body. Inflammation is the sum total of the body's reaction to infection, allergy, irritation, malignancy (cancer), or injury. The test is neither specific to a particular type of disease or condition, nor does it identify what tissues or organs are inflamed. In other words, while the sedimentation rate is a useful test to verify an impression of the possible presence of a particular illness, it cannot stand alone as a definitive diagnostic tool. The patient's history and symptoms must be correlated with the sedimentation rate and other laboratory tests in order to arrive at a clinical diagnosis.

The sedimentation rate is literally a measure of the distance that red blood cells (erythrocytes) fall through a test tube filled with blood in an hour's time. This process leaves clear plasma, devoid of red blood cells, at the top of the tube. When there is an inflammatory process occurring in the body, the body produces a variety of proteins that stick to red blood cells. These protein-red blood cell complexes are heavier than unaffected red blood cells, allowing them to fall more quickly and farther through the blood in the test tube. As a result, when inflammation is present in the body, the red blood cells drop through the test tube more quickly, and more of them accumulate at a lower part of the test tube, resulting in a higher sedimentation rate.

### Purpose

A sedimentation rate is usually done when an individual is having symptoms compatible with an inflammatory disorder, particularly polymyalgia rheumatica and temporal arteritis. Some symptoms that might prompt a practitioner to order a sedimentation rate include unexplained headache, joint pain or stiffness, anemia, unintentional weight loss, fevers, and severe fatigue. The sedimentation rate is also frequently used to monitor a disease process that has already been diagnosed, such as Hodgkin's lymphoma, or autoimmune disorders such as rheumatoid arthritis or systemic lupus erythematosus.

### Precautions

The sedimentation rate is not diagnostic. This means that getting a specific result does not definitively confirm the presence of any particular disease.

## KEY TERMS

**Autoimmune disorder**—A condition in which the body's immune system is accidentally attacking tissues or organs of the body, causing injury and disease.

**Inflammation**—Pain, swelling, redness, and heat that often occurs when tissues of the body are injured, infected, or irritated in some way.

**Malignancy**—Conditions that are cancerous, meaning that they produce abnormal cells capable of invading and destroying other local and distant tissues.

**Polymyalgia rheumatica**—A condition with symptoms of achiness and stiffness, primarily striking older adults.

**Temporal arteritis**—A condition in which inflammation of the blood vessels that supply the head and neck result in severe, chronic headache, particularly over one temple, as well as fever, weight loss, and severe fatigue.

Instead, the test is used to correlate with the clinical picture, meaning the history and the symptoms that an individual is experiencing.

### Description

This test requires blood to be drawn from a vein (usually one in the forearm), generally by a nurse or phlebotomist (an individual who has been trained to draw blood). A tourniquet is applied to the arm above the area where the needle stick will be performed. The site of the needle stick is cleaned with antiseptic, and the needle is inserted. The blood is collected in vacuum tubes. After collection, the needle is withdrawn, and pressure is kept on the blood draw site to stop any bleeding and decrease bruising. A bandage is then applied.

### Preparation

There are no restrictions on diet or physical activity, either before or after the blood test.

### Aftercare

As with any blood tests, discomfort, bruising, and/or a very small amount of bleeding is common at the puncture site. Immediately after the needle is withdrawn, it is helpful to put pressure on the puncture site until the bleeding has stopped. This decreases the chance of significant bruising. Warm packs may relieve minor discomfort. Some individuals may feel

briefly woozy after a blood test, and they should be encouraged to lie down and rest until they feel better.

### Risks

Basic blood tests, such as sedimentation testing, do not carry any significant risks, other than slight bruising and the chance of brief dizziness.

### Results

The normal sedimentation rate range in men is 0-15 mm/hour. The normal sedimentation rate range in women is 0-20 mm/hour. The normal sedimentation rate range in children is 0-10 mm/hour. The normal sedimentation rate range in newborn babies is 0-2 mm/hr. Women normally have higher sedimentation rates than men. People over the age of 50 years also have higher normal sedimentation rates than do younger individuals. Other factors that may increase the sedimentation rate without suggesting the presence of disease include obesity or pregnancy.

An elevated sedimentation rate can be caused by a number of conditions, including an episode of crisis in sickle cell disease, osteomyelitis, stroke, prostate cancer, coronary artery disease, rheumatoid arthritis, chronic infections, certain cancers (including Hodgkin's disease and renal cell carcinoma), ankylosing spondylitis, thyroid disease, temporal arteritis, scleroderma, polyarteritis nodosa, systemic lupus erythematosus, infections (appendicitis, osteomyelitis, pelvic inflammatory disease, pneumonia), and Kawasaki disease in children.

An extremely elevated sedimentation rate can be caused by multiple myeloma and polymyalgia rheumatica.

An abnormally low sedimentation rate can be caused by sickle cell anemia (not during painful crisis), use of steroid medications, polycythemia, or high serum glucose.

Segmental resection see **Segmentectomy**

## Segmentectomy

### Definition

Segmentectomy is the excision (removal) of a portion of any organ or gland. The procedure has several variations and many names, including segmental resection, wide excision, **lumpectomy**, tumorectomy, **quadrantectomy**, and partial **mastectomy**.

### Purpose

Segmentectomy is the surgical removal of a defined segment or portion of an organ or gland performed as a treatment. In this case, the purpose is the removal of a cancerous tumor. Common organs that have segments are the breasts, lungs, and liver.

### Demographics

Segmentectomies are usually performed on patients with lung, liver, or breast cancer.

Lung cancer is the second most common cancer among both men and women, and is the leading cause of cancer **death** for both genders. Lung cancer kills more people (approximately 157,000 per year) than cancers of the breast, prostate, colon, and pancreas combined. Almost 90% of all lung cancers are caused by cigarette smoking. Other causes include secondhand smoke and exposure to asbestos and other occupation-related substances.

In each of the racial and ethnic groups, the rates among men are about two to three times greater than the rates among women. Among men, age-adjusted lung cancer incidence rates (per 100,000) range from a low of about 14 among Native Americans to a high of 117 among African Americans, an eight-fold difference. For women, the rates range from approximately 15 per 100,000 among Japanese to nearly 51 among Alaska natives, approximately a three-fold difference.

Excluding cancers of the skin, breast cancer is the most common form of cancer among women in the United States. The increase in incidence is primarily due to increased screening by **physical examination** and **mammography**. Although breast cancer occurs among both women and men, it is quite rare among men. Caucasian non-Hispanic women have the highest rates of breast cancer, over twice the rate for Hispanic women. There are a low number of cases for Alaska native, Native American, Korean, and Vietnamese women.

Primary cancers of the liver account for approximately 1.5% of all cancer cases in the United States. About two-thirds of liver cancers are clearly associated with hepatitis B and hepatitis C viral infections and cirrhosis. This type of liver cancer occurs more frequently in men than in women by a ratio of two to one.

### Description

When cancer is confined to a segment of an organ, removal of that portion may offer cancer-control results equivalent to those of more extensive operations. This is especially true for breast and liver cancers. For breast and lung cancers, a segmentectomy is often combined with removal of some or all regional lymph nodes.

Treatment options for lung cancer depend on the stage of the cancer (whether it is in the lung only or has spread to other places in the body); tumor size; the type of lung cancer; presence (or lack) of symptoms; and the patient's general health.

A disease in which malignant (cancer) cells form in the tissues of the lung is called non-small cell lung cancer (NSCLC). There are five types of NSCLC; each consists of different types of cancer cells, which grow and spread in different ways. The types of NSCLC are named for the kinds of cells found in the cancer, and how the cells appear when viewed under a microscope.

Segmentectomy may be the treatment of choice for cancerous tumors in the occult, or hidden stage, as well as in stage 0, stage I, or stage II NSCLC. When the site and nature of the primary tumor is defined in occult stage lung cancer, it is generally removed by segmentectomy.

Segmentectomy is the usual treatment for stage 0 cancers of the lung, as they are limited to the layer of tissue that lines air passages, and have not invaded the nearby lung tissue. Chemotherapy or radiation therapy is not normally required.

Segmentectomy is recommended only for treating the smallest stage I cancers and for patients with other

## KEY TERMS

**Angiogram**—An examination of a part of the body by injecting dye into an artery so that the blood vessels show up on an x ray.

**Anterior mediastinotomy**—A surgical procedure to look at the organs and tissues between the lungs and between the breastbone and spine for abnormal areas. An incision (cut) is made next to the breastbone and a thin, lighted tube is inserted into the chest. Tissue and lymph node samples may be taken for biopsy.

**Biopsy**—Removal and examination of tissue, cells, or fluids from the living body.

**Bronchoscope**—A tubular illuminated instrument used for inspecting or passing instruments into the bronchi.

**Chemoprevention**—The use of drugs, vitamins, or other substances to reduce the risk of developing cancer or of the cancer returning.

**Chemotherapy**—Cancer treatment that uses drugs to stop the growth of cancer cells, either by killing the cells or by stopping them from dividing.

**Clinical breast exam**—An examination of the breast and surrounding tissue by a physician, who is feeling for lumps and looking for other signs of abnormality.

**Computed tomography**—An x-ray machine linked to a computer that takes a series of detailed pictures of the organs and blood vessels in the body.

**Conservation surgery**—Surgery that preserves the aesthetics of the area undergoing an operation.

**Excision**—To surgically remove.

**Excisional biopsy**—Procedure in which a surgeon removes all of a lump or suspicious area and an area of healthy tissue around the edges. The tissue is then examined under a microscope to check for cancer cells.

**Fine-needle aspiration**—A procedure in which a thin needle removes fluid and cells from a breast lump to be examined.

**Incisional biopsy**—A procedure in which a surgeon cuts out a sample of a lump or suspicious area.

**Laser therapy**—A cancer treatment that uses a laser beam (a narrow beam of intense light) to kill cancer cells.

**Lobectomy**—Removal of a section of the lung.

**Lymph node biopsy**—The removal of all or part of a lymph node to view under a microscope for cancer cells.

medical conditions that make removing part or the entire lobe of the lung (lobectomy) dangerous. If the patient does not have sufficient pulmonary function to tolerate this more extensive operation, a segmentectomy will be performed. Additional chemotherapy after surgery for stage I NSCLC is not routinely recommended. If a patient has serious medical problems, radiation therapy may be the primary treatment.

A cancerous tumor will be surgically removed by segmentectomy or lobectomy in cases of stage II NSCLC. A wedge resection might be done if the patient cannot withstand lobectomy. Sometimes **pneumectomy** (removal of the entire lung) is needed. Radiation therapy may be used to destroy cancer cells left behind after surgery, especially if malignant cells are present at the edge of the tissue removed by surgery. Some doctors may recommend additional radiation therapy even if the edges of the sample have no detectable cancer cells.

Segmentectomy is under investigation for the treatment of small-cell lung cancers.

Because of the need for radiotherapy after segmentectomy, some patients, such as pregnant women and those with syndromes not compatible with radiation treatment, may not be candidates for segmentectomy. As in any surgery, patients should alert their physician about all allergies and any medications they are taking.

### Diagnosis/Preparation

The following methods may be used to help diagnose breast cancer:

- complete physical exam and family medical history
- clinical breast exam
- mammography
- biopsy (incisional, excisional, or needle)
- ultrasonography
- fine-needle aspiration

Tests help to determine whether cancer cells have spread within the lungs or to other parts of the body after a diagnosis of lung cancer. The following tests

**Lymph nodes**—Small, bean-shaped organs located throughout the lymphatic system. Lymph nodes store special cells that can trap cancer cells and bacteria traveling through the body.

**Mammography**—An x ray of the breast

**Magnetic resonance imaging (MRI)**—A powerful magnet linked to a computer used to make detailed images of areas inside the body. These pictures are viewed on a monitor and can also be printed.

**Mediastinoscopy**—A surgical procedure to look at the organs, tissues, and lymph nodes between the lungs for abnormal areas. An incision (cut) is made at the top of the breastbone and a thin, lighted tube is inserted into the chest. Tissue and lymph node samples may be taken for biopsy.

**Needle biopsy**—The use of a needle to remove tissue from an area that looks suspicious on a mammogram but cannot be felt. Tissue removed in a needle biopsy goes to a lab to be checked for cancer cells.

**Photodynamic therapy**—A cancer treatment that uses a drug that is activated by exposure to light. When the drug is exposed to light, the cancer cells are killed.

**Positron emission tomography (PET) scan**—A procedure to find malignant tumor cells in the body. A

small amount of radionuclide glucose (sugar) is injected into a vein. The PET scanner rotates around the body and makes a picture of where the glucose is being used in the body. Malignant tumor cells show up brighter in the picture because they are more active and take up more glucose than normal cells.

**Radiation therapy**—A cancer treatment that uses high-energy x rays or other types of radiation to kill cancer cells.

**Radiologic exams**—The use of radiation or other imaging methods to find signs of cancer.

**Radiosurgery**—A method of delivering radiation directly to the tumor. This method does not involve surgery and causes little damage to healthy tissue.

**Radiotherapy**—The treatment of disease with high-energy radiation, such as x rays or gamma rays.

**Ultrasonography**—A procedure using high-frequency sound waves to show whether a lump is a fluid-filled cyst (not cancer) or a solid mass (which may or may not be cancer).

**Ultrasound test**—A device using sound waves that produce a pattern of echoes as they bounce off internal organs. The echoes create a picture of the organs.

and procedures may be used in the staging process to diagnose lung cancer:

- complete physical exam, including personal and family medical history
- chest x-ray
- computed tomography (CT) scan
- positron emission tomography (PET) scan
- other radiologic exams
- laboratory tests (tissue, blood, urine, or other substances in the body)
- bronchoscopy
- mediastinoscopy
- anterior mediastinotomy
- lymph node biopsy

Treatment is determined when the stage of the tumor is known.

Routine preoperative preparations, such as not eating or drinking after midnight on the night before surgery are typically ordered for a segmentectomy.

Information about expected outcomes and potential complications is also part of the preparation for this surgery.

## Aftercare

After a segmentectomy, patients are usually cautioned against doing moderate lifting for several days. Other activities may be restricted (especially if lymph nodes were removed) according to individual needs. Pain is often enough to limit inappropriate motion, and is generally controlled with medication. If pain medications are ineffective, the patient should contact the physician, as severe pain may be a sign of a complication requiring medical attention. Women who undergo segmentectomy of the breast are often instructed to wear a well-fitting support bra both day and night for approximately one week after surgery.

The length of the hospital stay depends on the specific surgery performed and the extent of organ or tissue removed, as well as other factors.

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

Segmentectomies are performed in a hospital by a general surgeon, a medical doctor who specializes in surgery. If there are complicating factors, a specialized surgeon may perform the surgery.

Radiation therapy usually begins four to six weeks after surgery, and continues for four to five weeks. The timing of additional therapy is specific to each patient.

### Risks

The risks for any surgical procedure requiring anesthesia include reactions to the medications and breathing problems. Bleeding and infection are risks for any surgical procedure. Infection in the area affecting a segmentectomy occurs in only 3–4% of patients. Pneumonia is also a risk.

### Normal results

Successful removal of the tumor with no major bleeding or infection at the wound site after surgery is considered a normal outcome.

### Morbidity and mortality rates

Although the incidence of breast cancer has been rising in the United States for the past two decades, the mortality rate has remained relatively stable since the 1950s. Mortality rates range from 15% of the incidence rate for Japanese women to 33% of the incidence rate for African American women. The highest age-adjusted mortality occurs among African American women, followed by Caucasian and Hawaiian women.

African American women have the highest mortality rates in the age groups 30–54 years and 55–69 years, followed by Hawaiian, and Caucasian non-Hispanic women. The mortality rate for Caucasian women exceeds that for African American women in the 70 year and older age group.

Five-year survival rates for liver cancer patients are usually less than 10% in the United States. The reported statistics for these cancers often include mortality rates that exceed the incidence rates. The discrepancy occurs when the cause of death is misclassified as “liver cancer” for patients whose cancer originated as a primary tumor in another organ and spread to the liver, becoming a secondary cancer.

## QUESTIONS TO ASK THE DOCTOR

- Is segmentectomy an option for treatment?
- When will it be known whether or not all the cancer has been removed?
- What benefits can be expected from this operation?
- What is the risk of tumor recurrence after undergoing this procedure?
- What should be done to prepare for surgery?
- What happens if this operation does not go as planned?

For primary liver cancer, non-Hispanic Caucasian men and women have the lowest age-adjusted mortality rates in the United States, roughly one-half that of the African American and Hispanic populations.

Liver cancer mortality rates for Asian American groups are several times higher than that of the Caucasian population. The highest age-adjusted mortality rates for all groups are among the Chinese population. Alaska Native and Native American populations have a very low incidence of liver cancer.

Factors that affect the prognosis (chance of recovery) for lung cancer include:

- stage of the cancer (whether it is in the lung only or has spread to other places in the body)
- tumor size
- type of lung cancer
- presence of symptoms
- shortness of breath during activities
- shortness of breath with less and less activity
- the patient’s general health

Current treatments are not a cure for most patients with non-small cell lung cancer. If it returns after treatment, it is called recurrent non-small cell lung cancer. The cancer may reappear in the brain, lung, or other parts of the body. Further treatment is then required.

### Alternatives

Other cancer treatments include:

- chemotherapy
- radiation therapy
- radiosurgery
- laser therapy
- photodynamic therapy
- chemoprevention

Using a segmentectomy to remove breast cancers (as a technique that conserves the aesthetic appearance of a breast) is being investigated for large tumors after several cycles of preoperative chemotherapy.

Cancers in some locations (such as where the windpipe divides into the left and right main bronchi) are difficult to remove completely by surgery without also removing an entire lung.

## Sentinel lymph node biopsy

### Definition

Sentinel lymph node biopsy (SLNB) is a minimally invasive procedure in which a lymph node near the site of a cancerous tumor is first identified as a sentinel node and then removed for microscopic analysis. SLNB was developed by researchers in several different cancer centers following the discovery that the human lymphatic system can be mapped with radioactive dyes, and that the lymph node(s) closest to a tumor serve to filter and trap cancer cells. These nodes are known as sentinel nodes because they act like sentries to warn doctors that a patient's cancer is spreading.

The first descriptions of sentinel nodes come from studies of penile and testicular cancers done in the 1970s. A technique that uses blue dye to map the lymphatic system was developed in the 1980s and applied to the treatment of melanoma in 1989. The extension of sentinel lymph node biopsy to the treatment of breast cancer began at the John Wayne Cancer Institute in Santa Monica, California, in 1991. As of 2003, SLNB is used in the diagnosis and treatment of many other cancers, including cancers of the head and neck, anus, bladder, lung, and male breast.

### Purpose

Sentinel lymph node biopsy has several purposes:

- Improving the accuracy of cancer staging. Cancer staging is a system that classifies malignant tumors according to the extent of their spread in the body. It is used to guide decisions about treatment.

At the site of a previous cancer removal, a radionuclide dye is injected (A and B). The area of maximum radioactivity is traced to a lymph node under the arm (C). The area is cut open, and the lymph node is identified by its blue dye (D). After the lymph node is removed, the area is checked for further radioactivity (E). (Illustration by GGS Information Services. Cengage Learning, Gale.)

- Catching the spread of cancer to nearby lymph nodes as early as possible.
- Defining homogeneous patient populations for clinical trials of new cancer treatments.

## Description

A sentinel lymph node biopsy is done in two stages. In the first part of the procedure, which takes one to two hours, the patient goes to the nuclear medicine department of the hospital for an injection of a radioactive tracer known as technetium 99. A doctor who specializes in nuclear medicine first numbs the area around the tumor with a local anesthetic and then injects the radioactive technetium. He or she usually injects a blue dye as well. The doctor will then use a gamma camera to take pictures of the lymph nodes before surgery. This type of imaging study is called lymphoscintigraphy.

After the lymphoscintigraphy, the patient must wait several hours for the dye and the radioactive material to travel from the tissues around the tumor to the sentinel lymph node. He or she is then taken to the **operating room** and put under **general anesthesia**. Next, the surgeon injects more blue dye into the area around the tumor. The surgeon then uses a hand-held probe connected to a gamma ray counter to scan the area for the radioactive technetium. The sentinel lymph node can be pinpointed by the sound made by the gamma ray counter. The surgeon makes an incision about 0.5 in long to remove the sentinel node. The blue dye that has been injected helps to verify that the surgeon is removing the right node. The incision is then closed and the tissue is sent to the hospital laboratory for examination.

## Preparation

Some cancer patients should not be given an SLNB. They include women with cancer in more than one part of the breast; women who have had previous breast surgery, including **plastic surgery**; women with breast cancer in advanced stages; and women who have had radiation therapy. Melanoma patients who have undergone wide excision (removal of surrounding skin as well as the tumor) of the original skin cancer are also not candidates for an SLNB.

Apart from evaluating the patient's fitness for an SLNB, no additional preparation is necessary.

## Aftercare

A sentinel lymph node biopsy does not require extensive aftercare. In most cases, the patient goes home after the procedure or after an overnight stay in the hospital.

## KEY TERMS

**Biopsy**—The removal of a piece of living tissue from the body for diagnostic purposes.

**Lymph**—A clear yellowish fluid derived from tissue fluid. It is returned to the blood via the lymphatic system.

**Lymph nodes**—Small masses of tissue located at various points along the course of the lymphatic vessels.

**Lymphedema**—Swelling of the arm as a result of removal of lymphatic tissue.

**Lymphoscintigraphy**—A technique for detecting the presence of cancer cells in lymph nodes by using a radioactive tracer.

**Prophylactic**—Intended to prevent or protect against disease.

**Sentinel lymph node**—The lymph node(s) closest to a cancerous tumor. They are the first nodes that receive lymphatic drainage from the tissues surrounding the tumor.

**Staging**—The classification of cancers according to the extent of the tumor.

The surgeon will discuss the laboratory findings with the patient. If the sentinel node was found to contain cancer cells, the surgeon will usually recommend a full axillary lymph node dissection (ALND). This is a more invasive procedure in which a larger number of lymph nodes—usually 12–15—is surgically removed. A drainage tube is placed for two to three weeks, and the patient must undergo physical therapy at home.

## Risks

Risks associated with an SLNB include the following:

- Mild discomfort after the procedure.
- Lymphedema (swelling of the arm due to disruption of the lymphatic system after surgery).
- Damage to the nerves in the area of the biopsy.
- Temporary discoloration of the skin in the area of the dye injection.
- False negative laboratory report. A false negative means that there is cancer in other lymph nodes in spite of the absence of cancer in the sentinel node. False negatives usually result from either poor timing of the dye injection, the way in which the pathologist

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

An SLNB is usually performed in a hospital that has a department of nuclear medicine, although it is sometimes done as an outpatient procedure. The radioactive material or dye is injected by a physician who specializes in nuclear medicine. The sentinel lymph node is removed by a surgeon with experience in the technique. It is then analyzed in the hospital laboratory by a pathologist, who is a doctor with special training in studying the effects of disease on body organs and tissues.

The accuracy of a sentinel lymph node biopsy depends greatly on the skill of the surgeon who removes the node. Recent studies indicate that most doctors need to perform 20–30 SLNBs before they achieve an 85% success rate in identifying the sentinel node(s) and 5% or fewer false negatives. They can gain the necessary experience through special residency programs, fellowships, or training protocols. It is vital for patients to ask their surgeon how many SLNBs he or she has performed, as those who do these biopsies on a regular basis generally have a higher degree of accuracy.

prepared the tissue for examination, or the existence of previously undiscovered sentinel nodes.

### Normal results

Sentinel lymph node biopsies have a high degree of accuracy, with relatively few false negatives. A negative laboratory report means that there is a greater than 95% chance that the other nearby lymph nodes are also free of cancer.

### Morbidity and mortality rates

Compared to axillary lymph node dissection, sentinel lymph node biopsy has a significantly lower rate of complications, including a lower rate of post-operative pain and infection, as well as a lower long-term risk of lymphedema.

### Alternatives

Breast cancer patients who should not have a sentinel lymph node biopsy usually undergo an axillary lymph node dissection to determine whether their cancer has spread. Melanoma patients who have already had a wide excision of the original melanoma

## QUESTIONS TO ASK THE DOCTOR

- Am I a candidate for sentinel lymph node biopsy?
- How many SLNBs have you performed?
- Do you perform this procedure on a regular basis?
- What is your false negative rate?

may have nearby lymph nodes removed to prevent the cancer from spreading. This procedure is called a prophylactic lymph node dissection.

## Septoplasty

### Definition

Septoplasty is a surgical procedure to correct the shape of the septum of the nose. The goal of this procedure is to correct defects or deformities of the septum. The nasal septum is the separation between the two nostrils. In adults, the septum is composed partly of cartilage and partly of bone. Septal deviations are either congenital (present from birth) or develop as

### Septoplasty

Septoplasty is used to correct a deviated septum (B). First an incision is made to expose the nasal septum (C). Pieces of septum that are obstructing air flow are removed (D), and the incision is then closed (E). (Illustration by GGS Information Services. Cengage Learning, Gale.)

a result of an injury. Most people with deviated septa do not develop symptoms. It is typically only the most severely deformed septa that produce significant symptoms and require surgical intervention. However, many septoplasties are performed during **rhinoplasty** procedures, which are most often performed for cosmetic purposes.

### Purpose

Septoplasty is performed to correct a crooked (deviated) or dislocated septum, often as part of **plastic surgery** of the nose (rhinoplasty). The nasal septum has three functions: to support the nose, to regulate air flow, and to support the mucous membranes (mucosa) of the nose. Septoplasty is done to correct the shape of the nose caused by a deformed septum or correct deregulated airflow caused by a deviated septum. Septoplasty is often needed when the patient is having an operation to reduce the size of the nose (reductive rhinoplasty), because this operation usually reduces the amount of breathing space in the nose.

During surgery, the patient's own cartilage that has been removed can be reused to provide support for the nose if needed. External septum supports are not usually needed. Splints may be needed occasionally to support cartilage when extensive cutting has been done. External splints can be used to support the cartilage for the first few days of healing. Tefla gauze is inserted in the nostril to support the flaps and cartilage and to absorb any bleeding or mucus.

### Demographics

About one-third of the population may have some degree of nasal obstruction. Among those with nasal obstruction, about one-fourth have deviated septa.

### Diagnosis/Preparation

The primary conditions that may suggest a need for septoplasty include:

- nasal air passage obstruction
- nasal septal deformity
- headaches caused by septal spurs
- chronic and uncontrolled nosebleeds
- chronic sinusitis associated with a deviated septum
- obstructive sleep apnea
- polypectomy (polyp removal)
- tumor excision
- turbinate surgery
- ethmoidectomy (removal of all or part of a small bone on the upper part of the nasal cavity)

## KEY TERMS

**Cartilage**—A tough, elastic connective tissue found in the joints, outer ear, nose, larynx, and other parts of the body.

**Obstructive sleep apnea**—A temporary cessation of breathing that occurs during sleep and is associated with poor sleep quality.

**Polyp**—A tumor commonly found in vascular organs such as the nose that are often benign but can become malignant.

**Rhinoplasty**—Plastic surgery of the nose.

**Septum (plural, septa)**—The dividing partition in the nose that separates the two nostrils. It is composed of bone and cartilage.

**Sinusitis**—Inflammation of the sinuses.

**Splint**—A thin piece of rigid material that is sometimes used during nasal surgery to hold certain structures in place until healing is underway.

**Spurs**—A sharp horny outgrowth of the skin.

**Wegener's granulomatosis**—A rare condition that consists of lesions within the respiratory tract.

Septal deformities can cause nasal airway obstruction. Such airway obstruction can lead to mouth breathing, chronic nasal infections, or obstructive sleep apnea. Septal spurs can produce headaches when these growths lead to increased pressure on the nasal septum. Polypectomy, ethmoidectomy, **tumor removal**, and turbinate surgical procedures often include septoplasty. Individuals who have used significant quantities of cocaine over a long period of time often require septoplasty because of alterations in the nasal passage structures.

Septal deviation is usually diagnosed by direct observation of the nasal passages. In addition, a computed tomography (CT) scan of the entire nasal passage is often performed. This scan allows the physician to fully assess the structures and functioning of the area. Additional tests that evaluate the movement of air through the nasal passages may also be performed.

Before performing a septoplasty, the surgeon will evaluate the difference in airflow between the two nostrils. In children, this assessment can be done very simply by asking the patient to breathe out slowly on a small mirror held in front of the nose.

As with any other operation under **general anesthesia**, patients are evaluated for any physical conditions that might complicate surgery and for any medications

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

Septoplasty is performed by a medical doctor (M.D.) who has received additional training in surgery. Typically, septoplasty is performed by a board-certified plastic surgeon, a specialist called an otolaryngologist, or a head and neck surgeon. The procedure can be performed in a hospital or in a specialized surgical clinic.

that might affect blood clotting time. If a general anesthetic is used, then the patient is advised not to drink or eat after midnight the night before the surgery. In many cases, septoplasty can be performed on an outpatient basis using **local anesthesia**. Conditions that might preclude a patient from receiving a septoplasty include excessive cocaine abuse, Wegener's granulomatosis, malignant lymphomas, and an excessively large septal perforation.

### Aftercare

Patients who receive septoplasty are usually sent home from the hospital later the same day or in the morning after the surgery. All **dressings** inside the nose are usually removed before the patient leaves. Aftercare includes a list of detailed instructions for the patient that focus on preventing trauma to the nose.

The head needs to be elevated while resting during the first 24-48 hours after surgery. Patients will have to breathe through the mouth while the nasal packing is still in place. A small amount of bloody discharge is normal, but excessive bleeding should be reported to the physician immediately. **Antibiotics** are usually not prescribed unless the packing is left in place more than 24 hours. Most patients do not suffer significant amounts of pain, but those who do have severe pain are sometimes given narcotic pain relievers. Patients are often advised to place an ice pack on the nose to enhance comfort during the recovery period. Patients who have splint placement usually return seven to 10 days after the surgery for examination and splint removal.

### Risks

The risks from septoplasty are similar to those from other operations on the face: postoperative pain

## QUESTIONS TO ASK THE PRIMARY CARE PHYSICIAN

- What are my alternatives?
- Is surgery the answer for me?
- Can you recommend a surgeon who performs septoplasty?
- If surgery is appropriate for me, what are the next steps?

with some bleeding, swelling, bruising, or discoloration. A few patients may have allergic reactions to the anesthetics. The operation in itself, however, is relatively low-risk in that it does not involve major blood vessels or vital organs. Infection is unlikely if proper surgical technique is observed. One of the extremely rare but serious complications of septoplasty is cerebrospinal fluid leak. This complication can be treated with proper nasal packing, bed rest, and antibiotic use. Follow-up surgery may be necessary if the nasal obstruction relapses.

### Normal results

Normal results include improved breathing and airflow through the nostrils, and an acceptable outward shape of the nose. Most patients have significant improvements in symptoms following surgery.

### Morbidity and mortality rates

Significant morbidity associated with septoplasty is rare and is outlined in the Risks section above. Mortality is extremely rare and associated with the risks involving anesthesia. This procedure can be performed using local anesthesia on an outpatient basis or under general anesthesia during a short hospital stay. General anesthesia is associated with a greater mortality rate, but this risk is minimal.

### Alternatives

In cases of sinusitis or allergic rhinitis, nasal airway breathing can be improved by using nasal sprays, such as phenylephrine (Neo-Synephrine). Patients with a history of chronic, uncontrolled nasal bleeding should receive conservative therapy that includes nasal packing to identify the source of the bleeding before surgery is contemplated. Those who have been diagnosed with obstructive sleep apnea have a variety of conservative alternatives before surgery is seriously considered. These alternatives include weight loss,

## QUESTIONS TO ASK THE SURGEON

How many times have you performed septoplasty?  
 Are you a board-certified surgeon?  
 What type of outcomes have you had?  
 What are the most common side effects or complications?  
 What should I do to prepare for surgery?  
 What should I expect following the surgery?  
 Can you refer me to one of your patients who has had this procedure?  
 What type of diagnostic procedures are performed to determine if patients require surgery?  
 Will I need to see another specialist for the diagnostic procedures?

changes in sleep posture, and the use of appliances during sleep that enlarge the upper airway.

## Serum chloride level

### Definition

Chloride is a mineral that is found throughout the body. Along with other electrolytes (such as sodium, potassium, and carbon dioxide), chloride is involved in maintaining an appropriate fluid balance throughout the body, including an appropriate blood volume; maintaining a stable blood pressure; and equilibrating the pH of the body fluids. For the body to function normally, serum chloride levels have to be maintained at a very narrow range; when chloride levels are too high or

too low, it can have serious health consequences. The body keeps its chloride levels in equilibrium by prompting the kidneys to resorb more (when the body needs chloride) or excrete more (when there is excess chloride). When serum chloride levels get too high, the condition is called hyperchloremia. When serum chloride levels get too low, the condition is called hypochloremia.

### Purpose

A serum chloride level is usually drawn as part of a larger panel of electrolytes. Other measurements in the electrolyte panel include sodium, potassium, and carbon dioxide. A serum chloride level is usually checked during a routine **physical examination**, as well as to evaluate patients who are experiencing prolonged or severe vomiting and/or diarrhea, fatigue, weakness, confusion, muscle spasms, or respiratory distress. Electrolyte panels are frequently used to diagnose, monitor, or otherwise evaluate patients with kidney disease, liver disease, high blood pressure, heart failure, and other chronic conditions.

### Precautions

Serum chloride levels can be affected by a number of medications. Patients who are on these medications should inform their doctor, so that test results can be interpreted appropriately. Medications that may affect serum chloride levels include steroid medications, **non-steroidal anti-inflammatory drugs** (such as ibuprofen), estrogen-containing medications, male hormones (androgens) some blood pressure medications, cholesterol-lowering agents (such as cholestyramine), and diuretic medications. Another factor that may skew the results of a serum chloride level involves the patient's level of hydration. When a patient is dehydrated, the serum chloride level will be elevated; when a patient is over-hydrated, the serum chloride level will be artificially lowered.

Patients who are taking anticoagulant medications should inform their healthcare practitioner, since this may increase their chance of bleeding or bruising after a blood test.

### Description

This test requires blood to be drawn from a vein (usually one in the forearm), generally by a nurse or phlebotomist (an individual who has been trained to draw blood). A tourniquet is applied to the arm above the area where the needle stick will be performed. The site of the needle stick is cleaned with antiseptic, and the needle is inserted. The blood is collected in vacuum tubes. After collection, the needle is withdrawn, and pressure is kept on the blood draw site to stop any bleeding and decrease bruising. A bandage is then applied.

## KEY TERMS

**Addison's disease**—A disease involving decreased functioning of the adrenal glands.

**Antidiuretic hormone (ADH)**—Also called vasopressin. A hormone produced by the hypothalamus and stored in and excreted by the pituitary gland. ADH acts on the kidneys to reduce the flow of urine, increasing total body fluid. When too much ADH is produced, resulting in the body retaining fluid, the sodium concentration becomes abnormally low.

**Cushing's syndrome**—A disorder affecting the adrenal glands and their secretion of cortisol.

**Diuretic**—A medication that increases the flow of urine through the kidneys and out of the body.

**Hyperchloremia**—Elevated serum chloride levels.

**Hypochloremia**—Low serum chloride levels.

**Metabolic acidosis**—A condition in which either too much acid or too little bicarbonate in the body results in a drop in the blood pH (towards acidity).

**Metabolic alkalosis**—A condition in which abnormal either too little acid or too much bicarbonate in the body results in an elevation in the blood pH (towards alkalinity).

**Respiratory acidosis**—A condition in which abnormal exchange of oxygen and carbon dioxide in the lungs results in too much carbon dioxide being accumulated, and a resultant drop in the blood pH (towards acidity).

**Respiratory alkalosis**—A condition in which abnormal exchange of oxygen and carbon dioxide in the lungs results in the exhalation of too much carbon dioxide, and a resultant rise in the blood pH (towards alkalinity).

## Preparation

There are no restrictions on diet or physical activity, either before or after the blood test.

## Aftercare

As with any blood tests, discomfort, bruising, and/or a very small amount of bleeding is common at the puncture site. Immediately after the needle is withdrawn, it is helpful to put pressure on the puncture site until the bleeding has stopped. This decreases the chance of significant bruising. Warm packs may relieve minor discomfort. Some individuals may feel briefly woozy after a blood test, and they should be encouraged to lie down and rest until they feel better.

## Risks

Basic blood tests, such as serum chloride levels, do not carry any significant risks, other than slight bruising and the chance of brief dizziness.

## Results

In adults, a normal serum chloride level is 98-106 milliequivalents per liter (mEq/L, or 98-106 millimoles per liter (mmol/L). In children, a normal serum chloride level is 90-110 milliequivalents per liter (mEq/L, or 90-110 millimoles per liter (mmol/L). In newborns, a normal serum chloride level is 96-106 milliequivalents per liter (mEq/L, or 96-106 millimoles per liter (mmol/L). In premature infants, a normal serum chloride level is 95-110 milliequivalents per liter (mEq/L, or 95-110 millimoles per liter (mmol/L).

### High levels

High serum chloride levels occur whenever there is low blood sodium (hyponatremia), or may also be due to:

- Dehydration: Increased loss of body water without sufficient replacement by drinking; often occurs in febrile illnesses, with severe diarrhea and/or vomiting, or in situations involving heavy exercise in hot weather, resulting in fluid loss through heavy sweating
- Hyperventilation
- Kidney disease
- Excessive consumption of salt
- Anemia
- Use of carbonic anhydrase inhibitors (glaucoma medications)
- Hyperparathyroidism (an overactive parathyroid gland)
- Metabolic acidosis
- Respiratory alkalosis
- Excess bromide

### Low levels

Low serum chloride levels may be due to any disorder that causes low blood sodium (hyponatremia) or may be due to:

- Cushing's syndrome
- Addison's disease
- Syndrome of inappropriate ADH secretion (SIADH)
- Repeated vomiting, or prolonged gastric suction
- Chronic diarrhea
- Serious burns
- Excess sweating

- Chronic lung diseases, including emphysema and chronic obstructive pulmonary disorder
- Congestive heart failure
- Kidney disease
- Cystic fibrosis
- Respiratory acidosis
- Metabolic alkalosis
- Overhydration

## Serum creatinine level

### Definition

Creatinine is actually a chemical waste product that is produced by the muscles. The chemical “creatinine” is an important chemical involved in the production of energy needed for muscle contraction. During the course of every day, about 2% of the body’s creatine becomes creatinine. Creatinine enters the bloodstream and goes to the kidneys. Healthy kidneys filter out this waste material from the blood. It passes into the urine and out of the body. Unhealthy kidneys are unable to filter out the creatinine from the blood. The creatinine remains circulating in the bloodstream, and levels rise as the muscles continue to produce more and more.

The serum creatinine level is used to predict how the kidneys are functioning. In many cases, the serum creatinine level will begin to rise before a patient is even aware of any symptoms of kidney malfunction. High creatinine levels indicate the need for further investigation into the possibility that kidney failure is ensuing. If a creatinine level is elevated, then other tests such as blood urea nitrogen (BUN) or urine

creatinine will be performed. Calculations involving serum and urine creatinine levels will give the creatinine clearance, a figure which reflects the capacity of the kidneys to filter small molecules out of the bloodstream. Calculations involving the serum creatinine level and the individual’s gender, height, weight, and age will allow estimation of the glomerular filtration rate, which can screen for kidney damage and disease.

Serum creatinine level is tied to muscle contraction, therefore, the normal value of an individual’s serum creatinine level will be dependent on the individual’s size and their overall muscle mass. In general, the normal serum creatinine level for men is higher than the normal serum creatinine level in either women or children. Because athletes tend to have greater muscle mass, their normal creatinine level may be higher than that of non-athletes.

### Purpose

A serum creatinine level is usually drawn as part of a larger metabolic panel or screen. Other tests performed in this panel include electrolytes (sodium, potassium, chloride, and carbon dioxide), as well as calcium, glucose, and BUN. A serum creatinine level is usually checked during a routine **physical examination**, as well as to evaluate patients for the presence of kidney disease, to monitor patients who have illnesses or who are taking medications that might affect the functioning of their kidneys, or to make sure that treatment for kidney disease is effective.

### Precautions

Serum creatinine levels can be affected by a number of medications. Patients who are on these medications should inform their doctor, so that test results can be interpreted appropriately. Medications that may affect serum creatinine levels include methyl-dopa, trimethoprim, vitamin C, cimetidine, certain **diuretics**, and cephalosporin **antibiotics**. Additionally, if the serum creatinine level is going to be used in calculations with the urine creatinine or the BUN levels to evaluate kidney functioning, results may be skewed by the following medications: vitamin C, phenytoin, cephalosporin antibiotics, captopril, aminoglycosides, trimethoprim, cimetidine, quinine, quinidine, procainamide, amphotericin B, steroid medications, and tetracycline antibiotics.

Patients who are taking anticoagulant medications should inform their healthcare practitioner, since this may increase their chance of bleeding or bruising after a blood test.

## KEY TERMS

**Blood urea nitrogen (BUN)**—Blood urea nitrogen is a chemical waste product of protein metabolism that circulates in the bloodstream. Healthy kidneys remove urea from the bloodstream and it leaves the body in the urine. When the kidneys are not functioning properly, they are unable to filter the urea out of the blood, and blood urea nitrogen levels become elevated.

**Creatine**—Creatine is a substance produced by proteins and stored in the muscles. Creatine is a source for energy, allowing muscle contraction to take place. Some creatine is converted to creatinine, and enters the bloodstream, where it is filtered out by healthy kidneys and leaves the body in the urine. When the kidneys are not functioning properly, creatinine levels in the blood become abnormally elevated.

**Diabetic nephropathy**—Kidney damage or disease brought on by the long-term effects of diabetes.

**Glomerulonephritis**—A condition in which the filtering structures within the kidneys become damaged, limiting the kidneys' ability to filter waste products from the blood.

**Preeclampsia**—A condition occurring in pregnancy in which high blood pressure leads to a number of complications, including a decreased ability of the kidneys to appropriately filter wastes from the blood.

**Urine creatinine level**—A value obtained by testing a 24-hour collection of urine for the amount of creatinine present.

## Description

This test requires serum to be drawn from a vein (usually one in the forearm), generally by a nurse or phlebotomist (an individual who has been trained to draw serum). A tourniquet is applied to the arm above the area where the needle stick will be performed. The site of the needle stick is cleaned with antiseptic, and the needle is inserted. The serum is collected in vacuum tubes. After collection, the needle is withdrawn, and pressure is kept on the serum draw site to stop any bleeding and decrease bruising. A bandage is then applied.

## Preparation

In the 24–48 hours prior to a serum creatinine level, patients should be advised to avoid strenuous **exercise** and to limit the amount of protein they ingest. Creatinine is a waste product of muscle contraction and, therefore, vigorous exercise in the 48 hours prior to a serum creatinine level could alter the results of the test. Similarly, ingesting more than eight ounces of meat

(particularly beef) or other protein sources in the 24 hours prior to the serum creatinine level may affect the results.

## Aftercare

As with any blood tests, discomfort, bruising, and/or a very small amount of bleeding is common at the puncture site. Immediately after the needle is withdrawn, it is helpful to put pressure on the puncture site until the bleeding has stopped. This decreases the chance of significant bruising. Warm packs may relieve minor discomfort. Some individuals may feel briefly woozy after a serum test, and they should be encouraged to lie down and rest until they feel better.

## Risks

Basic serum tests, such as serum creatinine levels, do not carry any significant risks, other than slight bruising and the chance of brief dizziness.

## Results

In adult men, a normal serum creatinine level is 0.6–1.2 milligrams per deciliter (mg/dL) or 53–106 micromoles/L (mcmol/L). In adult women, a normal serum creatinine level is 0.5–1.1 mg/dL or 44–97 mcmol/L. In teenagers, a normal serum creatinine level is 0.5–1.0 mg/dL. In children, a normal serum creatinine level is 0.3–0.7 mg/dL. In newborn babies, a normal serum creatinine level is 0.3–1.2 mg/dL.

## High levels

High serum creatinine levels suggest that the kidneys are suffering from damage or disease. Kidneys can be damaged by severe infections, shock, cancer, or conditions that limit the blood flow reaching the kidneys. High serum creatinine levels can also occur when the urinary tract is blocked, or due to:

- obstruction of the urinary tract from a kidney stone or tumor;
- acute tubular necrosis;
- diabetic nephropathy;
- pre eclampsia;
- glomerulonephritis;
- dehydration;
- heart failure;
- extreme blood loss;
- gout;
- muscular dystrophy;
- rhabdomyolysis (conditions resulting in the abnormal breakdown of muscle tissue);
- myasthenia gravis;

- acromegaly; or
- gigantism.

### Low levels

Low serum creatinine levels may be due to:

- abnormally low muscle mass, as may occur in muscle wasting diseases like muscular dystrophy, or due to aging;
- liver disease;
- extreme low-protein diets; or
- pregnancy

## Serum glucose level

### Definition

The serum glucose or blood sugar level is a measurement of the amount of a particular form of simple sugar in the blood. When carbohydrates are ingested, they are broken down in the intestines into component parts, including sugars such as glucose. Glucose is absorbed from the small intestine into the bloodstream. It circulates throughout the body and is used by all of the body's tissues and organs to generate the energy necessary for their normal functioning. In order for glucose to enter the body's cells, insulin must be present. Insulin is a hormone produced in and excreted by the pancreas. Insulin functions to allow the transport of glucose into the cells of the body, as well as being involved in the body's storage of excess glucose in the form of glycogen or triglycerides.

The blood levels of glucose and insulin are intimately related. When carbohydrates are metabolized after a meal, the blood glucose begins to rise. Under normal circumstances, the pancreas then secretes insulin, in an amount relative to the blood glucose elevation. Between meals, or after heavy exertion, glucose levels may begin to drop below a safe threshold for the body's cells (particular cells of the brain and nervous system). In response to this lowering of blood glucose, the pancreas secretes a different hormone, called glucagon. Glucagon prompts the liver to convert glycogen into glucose, thereby elevating the blood glucose back into a safe range.

Abnormal levels of blood glucose can be life-threatening. High blood glucose is termed hyperglycemia; low blood glucose is termed hypoglycemia. Either of these conditions can result in organ failure, severe brain damage, coma, or **death**. Diabetes occurs when the pancreas fails to produce normal amounts of insulin, or when it completely stops producing any insulin at all (this is often referred to as insulin-dependent or type I diabetes). Diabetes can also occur when cells of the body become less responsive to the effects of insulin (this is often referred to as insulin-resistance, or type II diabetes). Diabetes causes abnormal perturbations of the serum glucose level. Chronic high levels of serum glucose (which may occur in poorly controlled diabetes) can result in severe damage over time to the heart, the eyes, the kidneys, the circulatory system, and the nervous system. In diabetics, sudden, acute increases in the serum glucose level can result in the condition called diabetic ketoacidosis, in which the extremely high levels of blood glucose lead a life-threatening illness. Diabetics can also suffer from sudden drops in serum glucose levels; if untreated, glucose deprivation can affect the organs and tissues of the body and may also be life-threatening.

### Purpose

A serum glucose level is usually drawn as part of a larger metabolic panel or screen. Other tests performed in this panel include electrolytes (sodium, potassium, chloride, and carbon dioxide), as well as calcium, creatinine, and BUN (blood urea nitrogen). A serum glucose level is usually checked during a routine **physical examination** or may be performed specifically to screen for diabetes, especially when there is a strong family history of diabetes, or when an individual has other specific risk factors, such as being overweight.

Serum glucose levels are also an important part of monitoring the health of pregnant women since some women develop gestational diabetes during pregnancy. Untreated, this can result in problems with the baby as

well as the mother. Gestational diabetes in early pregnancy can cause birth defects (particularly of the brain and/or heart) and increase the chance of miscarriage. Gestational diabetes in the second and third trimesters can cause the baby to grow very large. The baby's size can result in problems for the mother during labor and delivery. Additionally, once the baby is born, it can suffer sudden hypoglycemia. In utero, the baby will have acclimated to its mother's high serum glucose levels by producing high levels of insulin. After birth, suddenly deprived of that glucose, the baby's relatively high insulin levels can result in severe hypoglycemia.

A serum glucose level may be ordered when there are symptoms suspicious of diabetes, such as excessive thirst and/or hunger, urinary frequency, unintentional weight loss, severe fatigue and weakness, and poor healing. The diagnosis of diabetes requires that a random high serum glucose level be confirmed by a high fasting serum glucose level or by abnormal results of an **oral glucose tolerance test**. Patients who are diabetic may also be required to check their own blood glucose one or more times a day, to make sure that their condition is under good control.

A serum glucose level may be ordered when there are symptoms suspicious of low blood sugar (hypoglycemia), such as shakiness, sweating, anxiety, confusion, dizziness, or fainting.

### Precautions

The serum glucose level is highly affected by when an individual has last eaten, therefore, appropriate interpretation of the test results must take this into consideration. Serum glucose levels may be examined under random conditions, after an eight to ten hour fast (referred to as a fasting serum glucose level); two hours after a meal has been completed (referred to as a two-hour post-prandial serum glucose level); or after an individual has been given a standardized amount of a glucose-containing beverage (referred to as an oral glucose tolerance test or OGTT).

Serum glucose levels can be affected by a number of medications. Patients who are on these medications should inform their doctor, so that test results can be interpreted appropriately. Medications that may affect serum glucose levels include birth control pills, high blood pressure medications, phenytoin, furosemide, triamterene, hydrochlorothiazide, niacin, propranolol, and steroid medications. Additionally, the use of alcohol, the use of caffeine, recent illness, infection, or emotional distress may affect test results.

Patients who are taking anticoagulant medications should inform their healthcare practitioner,

since this may increase their chance of bleeding or bruising after a blood test.

### Description

This test requires serum to be drawn from a vein (usually one in the forearm), generally by a nurse or phlebotomist (an individual who has been trained to draw serum). A tourniquet is applied to the arm above the area where the needle stick will be performed. The site of the needle stick is cleaned with antiseptic, and the needle is inserted. The serum is collected in vacuum tubes. After collection, the needle is withdrawn, and pressure is kept on the serum draw site to stop any bleeding and decrease bruising. A bandage is then applied.

Self-glucose testing is often performed one or more times per day by diabetics themselves. This involves using a special sharp instrument, called a lancet, to prick a finger. Frequently, these lancets are placed in a spring-loaded mechanism to make it easier to accomplish the finger prick. A drop of blood from this finger prick is then put onto a special strip of paper and slipped into a machine called a blood glucose meter. The meter gives a digital readout of the serum glucose level. Alternatively, the drop of blood can be put onto a special strip of test paper which changes color based on the glucose level; this is less accurate than the blood glucose meter.

### Preparation

There are no special preparations necessary prior to a random serum glucose level. For a two-hour post-prandial serum glucose level, the individual should be instructed to eat a meal exactly two hours before the blood draw. For a fasting serum glucose level, the individual should ingest nothing other than water for a minimum of eight hours prior to the blood draw. Diabetics may be asked to delay their morning dose of insulin or oral diabetes medication (oral hypoglycemic agents) prior to the blood draw.

### Aftercare

As with any blood tests, discomfort, bruising, and/or a very small amount of bleeding is common at the puncture site. Immediately after the needle is withdrawn, it is helpful to put pressure on the puncture site until the bleeding has stopped. This decreases the chance of significant bruising. Warm packs may relieve minor discomfort. Some individuals may feel briefly woozy after a serum test, and they should be encouraged to lie down and rest until they feel better.

## KEY TERMS

**Gestational diabetes**—A type of diabetes that occurs during pregnancy. Untreated, it can cause severe complications for the mother and the baby; however, it usually does not lead to long-term diabetes in either the mother or the child.

**Glucose**—A simple sugar that is the product of carbohydrate metabolism. It is the major source of energy for all of the organs and tissues of the body.

**Glucagon**—A hormone produced in the pancreas that is responsible for elevating blood glucose when it falls below a safe level for the body's organs and tissues.

**Glycogen**—The form in which glucose is stored in the body.

**Hyperglycemia**—Elevated blood glucose levels.

**Hypoglycemia**—Low blood glucose levels.

**Insulin**—A hormone produced by the pancreas that is responsible for allowing the body's cells to utilize glucose. The deficiency or absence of insulin is one of the causes of the disease diabetes.

**Insulinoma**—A tumor within the pancreas that produces insulin, potentially causing the serum glucose level to drop to dangerously low levels.

**Ketoacidosis**—A potentially life-threatening condition in which abnormally high blood glucose levels result in the blood become too acidic.

**Pancreas**—An organ located near the liver and stomach, responsible for various digestive functions. The pancreas produces insulin and glucagon, hormones that are responsible for maintaining safe blood levels of glucose.

## Risks

Basic blood tests, such as serum glucose levels, do not carry any significant risks, other than slight bruising and the chance of brief dizziness.

## Results

Normal results of a random serum glucose test range from 70–125 milligrams per deciliter (mg/dL). Normal results of a two-hour post-prandial serum glucose level range from 70–145 mg/dL. Normal results of a fasting serum glucose level range from 70–99 mg/dL.

### High levels

High serum glucose levels suggest the possibility of diabetes; however, a single high, random serum glucose

level is not sufficient for definitively diagnosing diabetes. The American Diabetes Association has specific criteria that must be met in order to diagnose diabetes. They require that results are verified through testing on a minimum of two different days. Levels indicative of diabetes are as follows:

- random serum glucose level of 200 mg/dL in the presence of actual symptoms of diabetes (such as increased thirst and/or hunger, urinary frequency, unintentional weight loss, weakness and fatigue, numbness/tingling in hands and feet, blurred vision, or erection problems;
- fasting serum glucose level of at least 126 mg/dL;
- two-hour oral glucose tolerance test of at least 200 mg/dL.

Individuals who don't meet the criteria for an actual diagnosis of diabetes, but who have a higher-than-normal fasting serum glucose level, also known as an impaired fasting glucose (ranging from 100 mg/dL to 125 mg/dL), have an increased risk of eventually developing diabetes, and should be followed closely. These individuals are considered to have "prediabetes."

Other causes of high serum glucose levels include:

- severe stress;
- heart attack;
- stroke;
- Cushing's syndrome;
- steroid medications; and
- acromegaly (elevated growth hormone).

### Low levels

Low serum glucose levels may be due to:

- the presence of an insulinoma (a tumor that secretes insulin);
- Addison's disease;
- hypothyroidism (underactive thyroid);
- pituitary gland tumor;
- liver disease, including cirrhosis;
- kidney disease;
- malnutrition;
- eating disorders, including anorexia nervosa; and
- inappropriate doses of medicines used to treat diabetes, such as insulin or oral hypoglycemic agents.

## Sestamibi scan

### Definition

A sestamibi scan is a highly sensitive and highly specific nuclear medicine test used to locate and image an overactive parathyroid gland in a patient with known hyperparathyroidism. Information from the

**Sestamibi scan.** (ISM / Phototake. Reproduced by permission.)

test can help with planning for surgery to remove the overactive gland.

Located in the neck behind the thyroid gland, the four parathyroid glands are pea-sized endocrine glands that are responsible for the production of parathyroid hormone or PTH. PTH is important in the balance of calcium and phosphate throughout the body.

Under normal conditions, low calcium concentrations in the bloodstream prompt the parathyroid gland to put out increased amounts of PTH. PTH acts on several areas of the body. It directs the kidneys to absorb calcium back into the body, rather than flushing it out of the body in the urine. It activates osteoclasts in bone to degrade bone material, releasing calcium for use in the body. It increases the activity of vitamin D, which allows more calcium to be absorbed in the intestine.

Hyperparathyroidism is usually due to the presence of an adenoma, a benign (not cancerous) growth on one or more of the parathyroid glands. A sestamibi scan is used to generate images of the parathyroid glands prior to surgery so that the surgeon knows which of the four glands will require removal. Surgery to remove a parathyroid gland is called a **parathyroidectomy**.

During a sestamibi scan, the patient is given an injection of the radioactive material technetium-99, bound to a tiny protein called sestamibi. Unlike normal parathyroid glands, adenomatous parathyroid glands absorb the radioactive material, permitting visualization and localization of the tumor or tumors on the scan images. This test can be performed in preparation for an operation to remove the parathyroid adenoma, or during the course of such an operation (intraoperatively).

### Purpose

Hyperparathyroidism is a condition in which one or more of the parathyroid glands become overactive. Too much bone is broken down, and too much calcium circulates in the bloodstream (termed hypercalcemia). The consequences of this excess bone breakdown and excess circulating calcium include:

- Weakness
- Fatigue
- Depression
- Aching
- Decreased appetite
- Heartburn
- Nausea and vomiting
- Constipation

- High blood pressure
- Confusion
- Difficulty thinking
- Poor memory
- Excess thirst
- Frequent urination
- Thinner, weaker bones
- Increased risk of bone fracture
- Kidney stones

Hyperparathyroidism is often considered idiopathic, which means that there is no known underlying cause of the disorder. In about 5% of people with parathyroidism, there is a family tendency for the disorder, such as Familial multiple endocrine neoplasia type 1 or familial hypocalciuric hypercalcemia.

About 100,000 people in the United States are diagnosed with hyperparathyroidism annually. Women are twice as likely to get the disorder than men, and it is more common in people over the age of 60.

### Description

Prior to starting the scanner for a sestamibi scan, radioactive contrast is injected through an IV in the patient's arm. The radionuclide (the technetium-99 bound to sestamibi molecules) circulates in the blood stream, concentrating in diseased parathyroid glands. The patient lies on an examination table, and a gamma camera is positioned over the patient's neck. The camera consists of a crystal detector that detects emitted radiation from the radioactive contrast. A computer converts the signal into a digital image of the parathyroid glands. Scanning is done immediately after injection of the radionuclide, and 1½ to 2 hours after injection. Each scan takes about 10 minutes.

### Preparation

There is nothing patients need to do in preparation for a sestamibi scan. To avoid confusing results, patients who have recently had another type of nuclear scan may need to wait several days to allow that radioactive tracer to leave their bodies, prior to undergoing a sestamibi scan.

Women who are pregnant or who think they may be pregnant are advised against undergoing a sestamibi scan. Women who are breastfeeding and who require a sestamibi scan should feed their baby with formula for two days following the procedure, and should pump and discard their breast milk, since it will be contaminated with the radioactive dye.

## KEY TERMS

**Adenoma**—A benign tumor of an endocrine gland.

**Hypercalcemia**—Excess concentration of calcium in the blood.

**Hyperparathyroidism**—A condition in which the parathyroid gland is overactive; usually caused by the presence of an adenoma on one or more of the glands.

**Parathyroidectomy**—An operation performed in order to remove one or more parathyroid gland.

**Thyroid gland**—An endocrine organ in the neck which produces thyroid hormone. Thyroid hormone is involved in important growth and metabolic processes throughout the body.

### Aftercare

There is no aftercare necessary following a sestamibi scan. The patient can return immediately to a normal diet and normal activities.

### Risks

A sestamibi scan poses very little risk to the patient. Rarely, a patient may have an allergy to the radioactive contrast utilized.

### Normal results

Normal results of a sestamibi scan would reveal no uptake of the radionuclide tracer in the neck, suggesting that no parathyroid adenoma is present.

### Abnormal results

An abnormal sestamibi scan will reveal an area where the radionuclide has been absorbed by a parathyroid adenoma. Even small, single adenomas on a parathyroid gland will “light up,” due to their tendency to absorb the radionuclide. This allows highly accurate localization of the exact area requiring operation. In some cases, a falsely positive sestamibi scan may occur in patients with thyroid disease.

## Sex reassignment surgery

### Definition

Also known as sex change or gender reassignment surgery, sex reassignment surgery is a procedure that changes genital organs from one gender to another.

### Purpose

There are two main reasons to alter the genital organs from one sex to another.

- Newborns with intersex deformities must be assigned to one sex or the other. These deformities represent intermediate stages between the primordial female genitals and the change into male genitals caused by male hormone stimulation.
- Both men and women occasionally believe they are physically a different sex than they are mentally and emotionally. This dissonance is so profound that they are willing to be surgically altered.

In both cases, technical considerations favor successful conversion to a female rather than a male. Newborns with ambiguous organs will almost always be assigned to the female gender unless the penis is at least an inch (2.5 cm) long. Whatever their chromosomes, they are much more likely to be socially well-adjusted as females, even if they cannot have children.

### Demographics

Reliable statistics are extremely difficult to obtain. Many sexual reassignment procedures are conducted in private facilities that are not subject to reporting requirements. Sexual reassignment surgery is often conducted outside of the United States. The number of gender reassignment procedures conducted in the United States each year is estimated at between 100

#### Sex change surgery

To change male genitalia to female genitalia, an incision is made into the scrotum (A). The flap of skin is pulled back, and the testes are removed (B). The skin is stripped from the penis but left attached, and a shorter urethra is cut (C). All but a stump of the penis is removed (D). The excess skin is used to create the labia (external genitalia) and vagina (E). (Illustration by GGS Information Services. Cengage Learning, Gale.)

## KEY TERMS

**Androgens**—A class of chemical compounds (hormones) that stimulates the development of male secondary sexual characteristics.

**Chromosomes**—The carriers of genes that determine gender and other characteristics.

**Estrogens**—A class of chemical compounds (hormones) that stimulates the development of female secondary sexual characteristics.

**Hysterectomy**—Surgical removal of the uterus.

**Oophorectomy**—Surgical removal of the ovaries.

and 500. The number worldwide is estimated to be two to five times larger.

## Description

Converting male to female anatomy requires removal of the penis, reshaping genital tissue to appear more female, and constructing a vagina. A vagina can be successfully formed from a skin graft or an isolated loop of intestine. Following the surgery, female hormones (estrogen) will reshape the body's contours and stimulate the growth of satisfactory breasts.

Female to male surgery has achieved lesser success due to the difficulty of creating a functioning penis from the much smaller clitoral tissue available in the female genitals. Penis construction is not attempted less than a year after the preliminary surgery to remove the female organs. One study in Singapore found that a third of the persons would not undergo the surgery again. Nevertheless, they were all pleased with the change of sex. Besides the genital organs, the breasts need to be surgically altered for a more male appearance. This can be successfully accomplished.

The capacity to experience an orgasm, or at least "a reasonable degree of erogenous sensitivity," can be expected by almost all persons after gender reassignment surgery.

## Diagnosis/Preparation

Gender identity is an extremely important characteristic for human beings. Assigning sex must take place immediately after birth for the mental health of both children and their parents. Changing sexual identity is among the most significant changes that a human can experience. It should therefore be undertaken with extreme care and caution. By the time most adults come to surgery, they have lived for many years

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

Gender reassignment surgery is performed by surgeons with specialized training in urology, gynecology, or plastic and reconstructive surgery. The surgery is performed in a hospital setting, although many procedures are completed in private clinics.

with a dissonant identity. The average in one study was 29 years. Nevertheless, even then they may not be fully aware of the implications of becoming a member of the opposite gender.

In-depth psychological counseling should precede and follow any gender reassignment surgical procedure.

Sex reassignment surgery is expensive. The cost for male to female reassignment is \$10,000 to \$20,000. The cost for female to male reassignment can exceed \$50,000.

## Aftercare

Social support, particularly from one's family, is important for readjustment as a member of the opposite gender. If surgical candidates are socially or emotionally unstable before the operation, over the age of 30, or have an unsuitable body build for the new gender, they tend not to fare well after gender reassignment surgery; however, in no case studied did the gender reassignment procedure diminish the ability to work.

## Risks

All surgery carries the risks of infection, bleeding, and a need to return for repairs. Gender reassignment surgery is irreversible, so a candidate must have no doubts about accepting the results and outcome.

## Normal results

Persons undergoing gender reassignment surgery can expect to acquire the external genitalia of a member of the opposite gender. Persons having male to female gender reassignment surgery retain a prostate. Individuals undergoing female to male gender reassignment surgery undergo a **hysterectomy** to remove the uterus and **oophorectomy** to remove their ovaries. Developing the habits and mannerisms characteristic of the patient's new gender requires many months or years.

## QUESTIONS TO ASK THE DOCTOR

Candidates for gender reassignment surgery should ask the following questions.

- What will my body look like afterward?
- Is the surgeon board certified in urology, gynecology, or plastic and reconstructive surgery?
- How many gender reassignment procedures has the surgeon performed?
- How many surgeries of the type similar to the one being contemplated (i.e., male to female or female to male) has the surgeon performed?
- What is the surgeon's complication rate?

### Morbidity and mortality rates

The risks that are associated with any surgical procedure are present in gender reassignment surgery. These include infection, postoperative pain, and dissatisfaction with anticipated results. Accurate statistics are extremely difficult to find. Intraoperative **death** has not been reported.

The most common complication of male to female surgery is narrowing of the new vagina. This can be corrected by dilation or using a portion of colon to form a vagina.

A relatively common complication of female to male surgery is dysfunction of the penis. Implanting a penile prosthesis is technically difficult and does not have uniformly acceptable results.

Psychiatric care may be required for many years after sex-reassignment surgery.

The number of deaths in male-to-female transsexuals was five times the number expected, due to increased numbers of suicide and death from an unknown cause.

### Alternatives

There is no alternative to surgical reassignment to alter one's external genitalia. The majority of persons who experience gender disorder problems never surgically alter their appearance. They dress as members of the desired gender, rather than gender of birth. Many use creams or pills that contain hormones appropriate to the desired gender to alter their bodily appearance. Estrogens (female hormones) will stimulate breast development, widening of the hips, loss of facial hair and a slight increase in voice pitch. Androgens (male hormones) will

stimulate the development of facial and chest hair and cause the voice to deepen. Most individuals who undergo gender reassignment surgery lead happy and productive lives.

## Shoulder joint replacement

### Definition

Shoulder joint replacement surgery is performed to replace a shoulder joint with artificial components (prostheses) when the joint is severely damaged by degenerative joint diseases such as arthritis, or in complex cases of upper arm bone fracture.

### Purpose

The shoulder is a ball-and-socket joint that allows the arms to be raised, twisted, bent, and moved forward, to the side and backward. The head of the upper arm bone (humerus) is the ball, and a circular cavity (glenoid) in the shoulder blade (scapula) is the socket. A soft-tissue rim (labrum) surrounds and deepens the socket. The head of the humerus is also covered with a smooth, tough tissue (articular cartilage), and the joint, also called the acromioclavicular (AC) joint, has a thin inner lining (synovium) that facilitates movement, while surrounding muscles and tendons provide stability and support.

The AC joint can be damaged by the following conditions to such an extent as to require replacement by artificial components:

- **Osteoarthritis.** This is a degenerative joint disease characterized by degeneration of the articular cartilage. When nonsurgical treatment is no longer effective and shoulder resection not possible, joint replacement surgery is usually indicated.
- **Rheumatoid arthritis.** Shoulder replacement surgery is the most commonly performed procedure for the arthritic shoulder with severe inflammatory or rheumatoid arthritis.
- **Severe fracture of the humerus.** A fracture of the upper arm bone can be so severe as to require replacement of the AC joint.
- **Osteonecrosis.** This condition usually follows a three- or four-part fracture of the humeral head that disrupts the blood supply, resulting in bone death and disruption of the AC joint.
- **Charcot's arthropathy.** Also called neuropathic arthropathy or arthritis, Charcot's arthropathy is a condition in which the shoulder joint is destroyed following loss of its nerve supply.

### Demographics

Shoulder arthritis is among the most prevalent causes of shoulder pain and loss of function. In the United States, arthritis of the shoulder joint is less common

than arthritis of the hip or knee. Individuals with arthritis in one joint are more likely to get it in another joint. Overall, arthritis is quite common in the United States, affecting about 21% of adult Americans, and 50% of American adults over the age of 65. Projections suggest that, by the year 2030, there will be 67 million Americans who have received the diagnosis of arthritis from their doctor. Osteoarthritis is also the most common joint disorder, extremely common by age 70. Men and women are equally affected, but onset is earlier in men.

### Description

Shoulder joint replacement surgery can either replace the entire AC joint, in which case it is referred to as total shoulder joint replacement or total shoulder **arthroplasty**; or replace only the head of the humerus, in which case the procedure is called a hemiarthroplasty.

### Implants

The two artificial components that can be implanted in the shoulder during shoulder joint replacement surgery are:

- **The humeral component.** This part replaces the head of the humerus. It is usually made of cobalt or chromium-based alloys and has a rounded ball attached to a stem that can be inserted into the bone. It comes in various sizes and may consist of a single piece or a modular unit.
- **The glenoid component.** This component replaces the glenoid cavity. It is made of very high-density polyethylene. Some models feature a metal tray, but the 100% polyethylene type is more common.

Shoulder joint replacement surgery is performed under either regional or **general anesthesia**, depending on the specifics of the case. The surgeon makes a 3–4 in (7.6–10.2 cm) incision on the front of the shoulder from the collarbone to the point where the shoulder muscle (deltoid) attaches to the humerus. The surgeon also inspects the muscles to see if any are damaged. He or she then proceeds to dislocate the humerus from the socket-like glenoid cavity to expose the head of the humerus. Only the portion of the head covered with articular cartilage is removed. The center cavity of the humerus (humeral shaft) is then cleaned and enlarged with reamers of gradually increasing size to create a cavity matching the shape of the implant stem. The top end of the bone is smoothed so that the stem can be inserted flush with the bone surface.

If the glenoid cavity of the AC joint is not damaged and the surrounding muscles are intact, the surgeon does not replace it, thus performing a simple hemiarthroplasty; however, if the glenoid cavity is

## Shoulder joint replacement

During a total shoulder joint replacement, an incision is first made in the shoulder and upper arm (A). The head of humerus is removed with a bone saw (B). The shaft of the humerus is reamed with a bone rasp to ready it for the prosthesis (C). After the shoulder joint, or glenoid cavity, is similarly prepared, bone cement is applied to areas to receive prostheses (D). The ball and socket prostheses are put in place, and the incision is closed (E). (Illustration by GGS Information Services. Cengage Learning, Gale.)

## KEY TERMS

**Acromioclavicular (AC) joint**—The shoulder joint. Articulation and ligaments between the collarbone and the acromion of the shoulder blade.

**Acromion**—The triangular projection of the spine of the shoulder blade that forms the point of the shoulder and articulates with the collarbone.

**Arthroplasty**—The surgical repair of a joint.

**Charcot's arthropathy**—Also called neuropathic arthropathy, a condition in which the shoulder joint is destroyed following loss of its nerve supply.

**Glenoid cavity**—The hollow cavity in the head of the shoulder blade that receives the head of the humerus to make the glenohumeral or shoulder joint.

**Humerus**—The bone of the upper part of the arm.

**Inflammatory arthritis**—An inflammatory condition that affects joints.

**Osteoarthritis**—Non-inflammatory degenerative joint disease occurring chiefly in older persons, characterized by degeneration of the articular cartilage.

**Osteonecrosis**—Condition resulting from poor blood supply to an area of a bone and causing bone death.

**Rheumatoid arthritis**—Chronic inflammatory disease that destroys joints.

**Shoulder resection arthroplasty**—Surgery performed to repair a shoulder acromioclavicular (AC) joint. The procedure is most commonly recommended for AC joint problems resulting from osteoarthritis or injury.

damaged or diseased, the surgeon moves the humerus to the back and implants the artificial glenoid component as well. The surgeon prepares the surface by removing the cartilage and equalizes the glenoid bone to match the implant. Protrusions on the polyethylene glenoid implant are then fitted into holes drilled in the bone surface. Once a precise fit is achieved, the implant is cemented into position. The humerus, with its new implanted artificial head, is replaced in the glenoid socket. The surgeon reattaches the supporting tendons and closes the incision.

## Diagnosis/Preparation

Damage to the AC joint is usually assessed using X-rays of the joint and humerus. They provide information on the state of the joint space, the position of the humeral head in relation to the glenoid, the

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

Shoulder replacement surgery is performed in a hospital by orthopedic surgeons with specialized training in shoulder joint replacement surgery.

presence of bony defects or deformity, and the quality of the bone. If glenoid wear is observed, a computed tomography (CT) scan is usually performed to evaluate the degree of bone loss.

The treating physician usually performs a general medical evaluation several weeks before shoulder joint replacement surgery to assess the patient's general health condition and risk for anesthesia. The results of this examination are forwarded to the orthopedic surgeon, along with a surgical clearance. Patients are advised to eat properly and take a daily iron supplement some weeks before surgery. Several types of tests are usually required, including blood tests, a cardiogram, a urine sample, and a chest X-ray. Patients may be required to stop taking certain medications until surgery is over.

## Aftercare

Following surgery, the operated arm is placed in a sling, and a support pillow is placed under the elbow to protect the repair. A drainage tube is used to remove excess fluid and is usually removed on the day after surgery.

A careful and well-planned rehabilitation program is very important for the successful outcome of a shoulder joint replacement. It should start no later than the first postoperative day. A physical therapist usually starts the patient with gentle, passive-assisted range of motion exercises. Before the patient leaves the hospital (usually two or three days after surgery), the therapist provides instruction on using a pulley device to help bend and extend the operated arm.

## Risks

Complications after shoulder replacement surgery occur less frequently than with other joint replacement surgeries; however, there are risks associated with the surgery, including infection, intra-operative fracture of the humerus or postoperative fractures, biceps tendon rupture, and postoperative instability and loosening of the glenoid implant. Advances in surgical

## QUESTIONS TO ASK THE DOCTOR

- What type of joint replacement surgery does my shoulder require?
- What are the risks associated with the surgery?
- How long will it take for my shoulder to recover from the surgery?
- How long will the artificial components last?
- Is there a risk of implant infection?
- How many shoulder joint replacement surgeries do you perform in a year?

techniques and prosthetic innovations are helping to significantly lower the occurrence of complications.

### Normal results

Pain relief is expected after shoulder joint replacement because the diseased joint surfaces have been replaced with smooth gliding surfaces. Improved motion, however, is variable and depends on the following:

- the surgeon's ability to reconstruct the shoulder's supporting tissues, namely the shoulder ligaments, capsule, and muscle attachments;
- the patient's preoperative muscle strength; and
- the patient's motivation and compliance in participating in postoperative rehabilitation therapy.

### Morbidity and mortality rates

Good to excellent outcomes usually follow shoulder joint replacement surgery, including pain relief and a functional range of motion that provides the ability to dress and perform the normal activities of daily living. In the hands of experienced orthopedic surgeons, such outcomes occur 90% of the time. Shoulders with artificial joints are reported to function well for more than 20 years. No **death** has ever been reported for shoulder joint replacement procedures.

### Alternatives

Arthritis treatment is very complex, as it depends on the type of arthritis and the severity of symptoms. Alternatives to joint replacement may include medications and therapy. It is known that arthritis is characterized by an increased rate of cartilage degradation and a decreased rate of cartilage production. An experimental therapy featuring the use of joint supplements such as glucosamine and chondroitin is being investigated for its

effectiveness to repair cartilage. The pain and inflammation resulting from arthritis are also commonly treated with nonsteroidal anti-inflammatory pain medication (NSAIDs) or cortisone injections (steroidal).

## Shoulder resection arthroplasty

### Definition

Shoulder resection **arthroplasty** is surgery performed to repair a shoulder acromioclavicular (AC) joint. The procedure is most commonly recommended for AC joint problems resulting from osteoarthritis or injury.

### Purpose

The shoulder consists of three bones: the shoulder blade, the upper arm bone (humerus), and the collarbone (clavicle). The part of the shoulder blade that makes up the roof of the shoulder is called the acromion and the joint where the acromion and the collarbone join is called the acromioclavicular (AC) joint.

## KEY TERMS

**Acromioclavicular dislocation**—Disruption of the normal articulation between the acromion and the collarbone. The acromioclavicular joint (AC joint) is normally stabilized by several ligaments that can be torn in the process of dislocating the AC joint.

**Acromioclavicular (AC) joint**—Articulation and ligaments between the collarbone and the acromion of the shoulder blade.

**Acromion**—The triangular projection of the spine of the shoulder blade that forms the point of the shoulder and articulates with the collarbone.

**Arthroplasty**—The surgical repair of a joint.

**Arthrosis**—A disease of a joint.

**Glenoid cavity**—The hollow cavity in the head of the shoulder blade that receives the head of the humerus to make the glenohumeral or shoulder joint.

**Osteoarthritis**—Non-inflammatory degenerative joint disease occurring chiefly in older persons, characterized by degeneration of the articular cartilage.

Some joints in the body are more likely to develop problems due to normal wear and tear, or degeneration resulting from osteoarthritis, a progressive and degenerative joint disease. The AC joint is a common target for developing osteoarthritis in middle age. This condition can lead to pain and difficulty using the shoulder for everyday activities. Besides osteoarthritis, AC joint disease (arthrosis) may develop from an old injury to the joint such as an acromioclavicular dislocation, which is the disruption of the normal articulation between the acromion and the collarbone. This type of injury is quite common in competitive sports, but can also result from a simple fall on the shoulder.

The goal of shoulder resection arthroplasty is to restore function to an impaired shoulder, with its required motion range, stability, strength, and smoothness.

## Demographics

According to the National Ambulatory Medical Care Survey, osteoarthritis is one of the most common confirmed diagnoses in individuals over the age of 65, with the condition starting to develop in middle age.

As for AC joint injuries, they are seen especially in high-level athletes such as football or hockey players, and occur most frequently in the second decade of life.

Males are more commonly affected than females, with a male-to-female ratio of approximately five to one.

## Description

A resection arthroplasty involves the surgical removal of the last 0.5 in (1.3 cm) of the collarbone. This removal leaves a space between the acromion and the cut end of the collarbone where the AC joint used to be. The joint is replaced by scar tissue, which allows movement to occur, but prevents the rubbing of the bone ends. The end result of the surgery is that the flexible connection between the acromion and the collarbone is restored. The procedure is usually performed by making a small 2 in (5 cm) incision in the skin over the AC joint. In some cases, the surgery can be done arthroscopically. In this approach, the surgeon uses an endoscope to look through a small hole into the shoulder joint. The endoscope is an instrument of the size of a pen, consisting of a tube fitted with a light and a miniature video camera, which transmits an image of the joint interior to a television monitor. The surgeon proceeds to remove the segment of collarbone through a small incision with little disruption of the other shoulder structures.

## Diagnosis/Preparation

The diagnosis is made by physical exam. Tenderness over the AC joint is usually present, with pain upon compression of the joint. X-rays of the AC joint may show narrowing of the joint and bone spurs around the joint. A **magnetic resonance imaging (MRI)** scan may also be performed. An MRI scan is a special imaging test that uses magnetic waves to create pictures that show the tissues of the shoulder in slices and has the advantage of showing tendons as well as bones. In some cases, an **ultrasound** test may be also be performed to inspect the soft tissues of the joint.

Prior to arthroplasty surgery, all the standard preoperative blood and urine tests are performed. The patient also meets with the anesthesiologist to discuss any special conditions that may affect the administration of anesthesia.

## Aftercare

The rehabilitation following surgery for a simple resection arthroplasty is usually fairly rapid. Patients should expect the soreness to last for three to six weeks. Postoperatively, patients usually have the affected arm in a sling for two weeks. Thereafter, a progressive passive range of shoulder motion **exercise** is started, usually with range-of-motion exercises that gradually evolve into active stretching and strengthening. The patient's arm

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

Shoulder resection arthroplasty is performed in a hospital. It is performed by experienced orthopedic surgeons who are specialists in AC joint problems. Some medical centers specialize in joint surgery and tend to have higher success rates than less specialized centers.

remains in the sling between sessions. At six weeks, healing is sufficient to encourage progressive functional use. Physiotherapy usually continues until range of motion and strength are maximized. The therapist may also use massage and other types of hands-on treatments to ease muscle spasm and pain. Heavy physical use of the shoulder is prohibited for an additional six weeks.

### Risks

Patients who undergo shoulder resection arthroplasty are susceptible to the same complications associated with any such surgery. These include wound infection, osteomyelitis, soft tissue ossification, and failure of fixation (remaining in place), with recurrent deformity. Symptomatic AC joint arthritis may develop in patients who undergo the surgery as a result of injury.

Specific risks associated with shoulder resection arthroplasty include:

- Fractures. Fractures of the humerus may occur after surgery, although the risk is considered low.
- Shoulder instability. Shoulder dislocations may occur during the early postoperative period due to soft tissue imbalance or to inadequate postoperative protection; late dislocation may result from glenoid cavity wear.
- Degenerative changes. Progressive degeneration of the AC joint is a common late complication.

### Normal results

Shoulder resection arthroplasty is generally very effective in reducing pain and restoring motion of the shoulder.

### Morbidity and mortality rates

In a four-year follow-up study on shoulder arthroplasty patients, all patients experienced pain relief. Functional improvement was good in 77% of patients. Average shoulder abduction improved from 37–79°

## QUESTIONS TO ASK THE DOCTOR

- How can I regain the use of my shoulder?
- What will it take to make my shoulder healthy again?
- Why do I have problems with my shoulder?
- What surgical procedures do you follow?
- How many shoulder resection arthroplasties do you perform each year?
- Will surgery on my shoulder condition allow me to resume my activities?

and forward flexion from 52–93°. No deaths resulting from shoulder resection arthroplasty have ever been reported.

### Alternatives

#### *Non-surgical treatments*

Doctors commonly attempt to treat AC joint problems using conservative treatments. Patients may be prescribed anti-inflammatory medications such as **aspirin** or ibuprofen. Treatment also may include disease-modifying drugs such as methotrexate and sulfasalazine, as well as gold injections. Researchers are also working on biologic agents that can interrupt the progress of osteoarthritis. These agents target specific chemicals in the body to prevent them from acting on the joints. Resting the sore joint and applying ice to it can also ease pain and inflammation. Injections of cortisone into the joint may also be prescribed. Cortisone is a strong steroidal medication that decreases inflammation and reduces pain. The effects of the drug are temporary, but it provides effective relief in the short term. Physicians may also prescribe sessions with a physical or occupational therapist, who may use various treatments to relieve inflammation of the AC joint, including heat and ice.

#### *Surgical alternatives*

Alternative surgical approaches include replacing the entire shoulder joint with a prosthesis (total shoulder arthroplasty) or replacing the head of the humerus (hemiarthroplasty).

Monique Laberge, Ph.D.

bowel disease, cancer, precancerous conditions, or causes of bleeding or pain.

### Purpose

Sigmoidoscopy is used most often in screening for colorectal cancer or to determine the cause of rectal bleeding. It is also used in diagnosis of inflammatory bowel disease, microscopic and ulcerative colitis, and Crohn's disease.

Cancer of the rectum and colon is the second most common cancer in the United States. About 148,300 new cases are diagnosed annually. Between 55,000 and 60,000 Americans die each year of cancer in the colon or rectum.

After reviewing a number of studies, experts recommend that people over 50 be screened for colorectal cancer using sigmoidoscopy every three to five years. Individuals with inflammatory bowel conditions such as Crohn's disease or ulcerative colitis, and thus at increased risk for colorectal cancer, may begin their screenings at a younger age, depending on when their disease was diagnosed. Many physicians screen such persons more often than every three to five years. Screening should also be performed in people who have a family history of colon or rectal cancer, or small growths in the colon (polyps).

Some physicians do this screening with a colonoscope, which allows them to see the entire colon. Most physicians prefer sigmoidoscopy, which is less time-consuming, less uncomfortable, and less costly.

Studies have shown that one-quarter to one-third of all precancerous or small cancerous growths can be seen with a sigmoidoscope. About one-half are found with a 1 ft (30 cm) scope, and two-thirds to three-quarters can be seen using a 2 ft (60 cm) scope.

In some cases, the sigmoidoscope can be used therapeutically in conjunction with other equipment such as electrosurgical devices to remove polyps and other lesions found during the sigmoidoscopy.

### Demographics

Experts estimate that in excess of 525,000 sigmoidoscopy procedures are performed each year. This number includes most of the persons who are diagnosed with colon cancer each year, a greater number who are screened and receive negative results, persons who have been treated for colon conditions and receive a sigmoidoscopy as a follow-up procedure, and individuals who are diagnosed with other diseases of the large colon.

## Sigmoidoscopy

### Definition

Sigmoidoscopy is a diagnostic and screening procedure in which a rigid or flexible tube with a camera on the end (a sigmoidoscope) is inserted into the anus to examine the rectum and lower colon (bowel) for

(Illustration by GGS Information Services. Cengage Learning, Gale.)

### Description

Sigmoidoscopy may be performed using either a rigid or flexible sigmoidoscope. A sigmoidoscope is a thin tube with fiberoptics, electronics, a light source, and camera. A physician inserts the sigmoidoscope into the anus to examine the rectum (the first 1 ft [30 cm] of the colon) and its interior walls. If a 2 ft (60 cm) scope is used, the next portion of the colon can also be examined for any irregularities. The camera of the sigmoidoscope is connected to a viewing monitor, allowing the interior of the rectum and colon to be enlarged and viewed on the monitor. Images can then be recorded as still pictures or the entire procedure can be videotaped. The still pictures are useful for comparison purposes with the results of future sigmoidoscopic examinations.

If polyps, lesions, or other suspicious areas are found, the physician biopsies them for analysis. During the sigmoidoscopy, the physician may also use forceps,

graspers, snares, or electrosurgical devices to remove polyps, lesions, or tumors.

A typical sigmoidoscopy procedure requires 15 to 20 minutes to perform. Preparation begins one day before the procedure. There is some discomfort when the scope is inserted and throughout the procedure, similar to that experienced when a physician performs a rectal exam using a finger to test for occult blood in the stool (another important screening test for colorectal cancer). Individuals may also feel some minor cramping pain. There is rarely severe pain, except for persons with active inflammatory bowel disease.

**Private insurance plans** almost always cover the cost of sigmoidoscopy examinations for screening in healthy individuals over 50, or for diagnostic purposes. **Medicare** covers the cost for diagnostic exams, and may cover the costs for screening exams. **Medicaid** benefits vary by state, but sigmoidoscopy is not a covered procedure in many states. Some community health clinics offer the

## KEY TERMS

**Biopsy**—The removal of a small portion of tissue during sigmoidoscopy to perform laboratory tests to determine if the tissue is cancerous.

**Colonoscopy**—A diagnostic endoscopic procedure that uses a long flexible tube called a colonoscope to examine the inner lining of the entire colon; may be used for colorectal cancer screening or for a more thorough examination of the colon.

**Colorectal cancer**—Cancer of the large intestine, or colon, including the rectum.

**Electrosurgical device**—A medical device that uses electrical current to cauterize or coagulate tissue during surgical procedures, often used in conjunction with laparoscopy, colonoscopy, or sigmoidoscopy.

**Inflammatory bowel diseases**—Ulcerative colitis or Crohn's disease: chronic conditions characterized by periods of diarrhea, bloating, abdominal cramps, and pain, sometimes accompanied by weight loss and malnutrition because of the inability to absorb nutrients.

**Pathologist**—A doctor who specializes in the diagnosis of disease by studying cells and tissues under a microscope.

**Polyp**—A small growth, usually not cancerous, but often precancerous when it appears in the colon.

procedure at reduced cost, but this can only be done if a local gastroenterologist (a physician who specializes in treating stomach and intestinal disorders) is willing to donate personal time to perform the procedure.

## Diagnosis/Preparation

The purpose of preparation for sigmoidoscopy is to cleanse the lower bowel of fecal material or stool so the physician can see the lining. Preparation begins 24 hours before the procedure, when an individual must begin a clear liquid diet. Preparation kits are available in drug stores. In normal preparation, about 20 hours before the exam, a person begins taking a series of **laxatives**, which may be oral tablets or liquid. The individual must stop drinking any liquid four hours before the exam. An hour or two prior to the examination, the person uses an enema or laxative suppository to finish cleansing the lower bowel.

Individuals need to be careful about medications before having sigmoidoscopy. They should not take **aspirin**, products containing aspirin, or products

containing ibuprofen for one week prior to the exam, because these medications can exacerbate bleeding during the procedure. They should not take any iron or vitamins with iron for one week prior to the exam, since iron can cause color changes in the bowel lining that interfere with the examination. They should take any routine prescription medications, but may need to stop certain medications. Prescribing physicians should be consulted regarding routine prescriptions and their possible effect(s) on sigmoidoscopy.

Individuals with renal insufficiency or congestive heart failure need to be prepared in an alternative way, and must be carefully monitored during the procedure.

## Aftercare

There is no specific aftercare necessary following sigmoidoscopy. If a biopsy was taken, a small amount of blood may appear in the next stool. Persons should be encouraged to pass gas following the procedure to relieve any bloating or cramping that may occur after the procedure. In addition, an infection may develop following sigmoidoscopy. Persons should be instructed to call their physician if a fever or pain in the abdomen develops over the few days after the procedure.

## Risks

There is a slight risk of bleeding from the procedure. This risk is heightened in individuals whose blood does not clot well, either due to disease or medication, and in those with active inflammatory bowel disease. Rarely, trauma to the bowel or other organs can occur, resulting in an injury (perforation) that must be repaired, or peritonitis, which must be treated with medication.

Sigmoidoscopy may be contraindicated in persons with severe active colitis or toxic megacolon (an extremely dilated colon). In general, people experiencing continuous ambulatory peritoneal dialysis are not candidates due to a high risk of developing intraperitoneal bleeding.

## Normal results

The results of a normal examination reveal a smooth colon wall, with sufficient blood vessels for good blood flow.

## Morbidity and mortality rates

For a cancer screening sigmoidoscopy, an abnormal result is one or more noncancerous or precancerous polyps, or clearly cancerous polyps. People with polyps have an increased risk of developing colorectal cancer in the future and may be required to undergo

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

A colonoscopy procedure is usually performed by a gastroenterologist, a physician with specialized training in diseases of the colon. Alternatively, general surgeons or experienced family physicians perform sigmoidoscopic examinations. In the United States, the procedure is usually performed in an outpatient facility of a hospital or in a physician's professional office.

Persons with rectal bleeding may need full colonoscopy in a hospital setting. Individuals whose blood does not clot well (possibly as a result of blood-thinning medications) may require the procedure to be performed in a hospital setting.

additional procedures such as **colonoscopy** or more frequent sigmoidoscopic examinations.

Small polyps can be completely removed. Larger polyps may require the physician to remove a portion of the growth for laboratory biopsy. Depending on the laboratory results, a person is then scheduled to have the polyp removed surgically, either as an urgent matter if it is cancerous, or as an elective procedure within a few months if it is noncancerous.

In a diagnostic sigmoidoscopy, an abnormal result shows signs of active inflammatory bowel disease, either a thickening of the intestinal lining consistent with ulcerative colitis, or ulcerations or fissures consistent with Crohn's disease.

Mortality from a sigmoidoscopy examination is rare and is usually due to uncontrolled bleeding or perforation of the colon.

### Alternatives

A screening examination for colorectal cancer is a test for fecal occult blood. A dab of fecal material from toilet tissue is smeared onto a card. The card is treated in a laboratory to reveal the presence of bleeding. This test is normally performed prior to a sigmoidoscopic examination.

A less invasive alternative to a sigmoidoscopic examination is an X-ray of the colon and rectum. Barium is used to coat the inner walls of the colon. This lower GI (gastrointestinal) X-ray may reveal the outlines of suspicious or abnormal structures. It has the disadvantage of not allowing direct visualization

## QUESTIONS TO ASK THE DOCTOR

- Is the supervising physician appropriately certified to conduct a sigmoidoscopy?
- How many sigmoidoscopy procedures has the doctor performed?
- What other steps will be taken as a result of my test findings?

of the colon. It is less costly than a sigmoidoscopic examination.

A more invasive procedure is direct visualization of the colon during surgery. This procedure is rarely performed in the United States.

L. Fleming Fallon, Jr., M.D., Dr.P.H.

## Simple mastectomy

### Definition

Simple **mastectomy** is the surgical removal of one or both breasts. The adjacent lymph nodes and chest muscles are left intact. If a few lymph nodes are removed, the procedure is called an extended simple mastectomy. Breast-sparing techniques may be used to preserve the patient's breast skin and nipple, which is helpful in cosmetic **breast reconstruction**.

### Purpose

Removal of a patient's breast is usually recommended when cancer is present in the breast or as a

prophylactic when the patient has severe fibrocystic disease and a family history of breast cancer. The choice of a simple mastectomy may be determined by evaluating the size of the breast, the size of the cancerous mass, where the cancer is located, and whether any cancer cells have spread to adjacent lymph nodes or other parts of the body. If the cancer has not been contained within the breast, it calls for a **modified radical mastectomy**, which removes the entire breast and all of the adjacent lymph nodes. Only in extreme circumstances is a radical mastectomy, which also removes part of the chest wall, indicated.

A larger tumor usually is an indication of more advanced disease and will require more extensive surgery such as a simple mastectomy. In addition, if a woman has small breasts, the tumor may occupy more area within the contours of the breast, necessitating a simple mastectomy in order to remove all of the cancer.

Very rapidly growing tumors usually require the removal of all breast tissue. Cancers that have spread to adjacent tissues such as the chest wall or skin make simple mastectomy a good choice. Similarly, multiple sites of cancer within a breast require that the entire breast be removed. In addition, simple mastectomy is also recommended when cancer recurs in a breast that has already undergone a **lumpectomy**, which is a less invasive procedure that just removes the tumor and some surrounding tissue without removing the entire breast.

Sometimes, surgeons recommend simple mastectomy for women who are unable to undergo the adjuvant radiation therapy required after a lumpectomy. Radiation treatment is not indicated for pregnant women, those who have had previous therapeutic radiation in the chest area, and patients with collagen vascular diseases such as scleroderma or lupus. In these cases, simple mastectomy is the treatment of choice.

Some women with family histories of breast cancer and who test positive for a cancer-causing gene choose to have one or both of their breasts removed as a preventative for future breast cancer. This procedure is highly controversial. Though prophylactic mastectomy reduces the occurrence of breast cancer by 90% in high-risk patients, it is not a foolproof method. There has been some incidence of cancer occurring after both breasts were removed.

### Demographics

According to the American Cancer Society in 2003, it was estimated that more than 260,000 new cases of breast cancer in women would occur that year. New cases of breast cancer in men were expected to reach

**In a simple mastectomy, the skin over the tumor is cut open (A). The tumor and tissue surrounding it is removed (B), and the wound is closed (C). (Illustration by GGS Information Services. Cengage Learning, Gale.)**

1,300. Rates of incidence have increased since 1980, due in part to the aging of the population. During the 1990s, breast cancer incidence increased only in women age 50 and over.

For approximately 80% of women, the first indication of cancer is the discovery of a lump in the breast, found either by themselves in a monthly self-exam or by a partner or by a mammogram, a special X-ray of the breast that looks for anomalies. Early detection of breast cancer means that smaller tumors are found, which require less intensive surgery and have better treatment outcomes. Simple mastectomy

has been the standard treatment of choice for breast cancer for the past 60 years. Newer breast-conserving surgery techniques have gained acceptance since the mid-1980s. For larger hospitals, facilities in urban areas, and health care institutions with a cancer center or high cancer patient volume, these newer techniques are being utilized at a more rapid rate, especially on the East Coast.

In 2003, the National Cancer Institute found that American women were 21% more likely to have a mastectomy than their counterparts in the United Kingdom. Though breast-conserving procedures are

## KEY TERMS

**Lumpectomy**—A less-invasive procedure that just removes the tumor and some surrounding tissue, without removing the entire breast.

**Lymphedema**—Swelling, usually of the arm after a mastectomy, caused by the accumulation of fluid from faulty drainage in the lymph system.

**Mammogram**—A special X-ray of the breast that looks for anomalies in the breast.

available and have proven to be viable options, some physicians and women still think breast removal will also remove all of their risk of cancer recurrence. It is clear that treatment options for cancer are highly individual and often emotionally charged.

## Description

Simple mastectomy is one of several types of surgical treatments for breast cancer. Some techniques are rarely used; others are quite common. These common surgical procedures include:

- **Radical mastectomy.** Radical mastectomy is rarely used, and then only in cases where cancer cells have invaded the chest wall and the tumor is very large. The breast, muscles under the breast, and all of the lymph nodes are removed. This produces a large scar and severe disability to the arm nearest the removed breast.
- **Modified radical mastectomy.** Modified radical mastectomy was the most common form of mastectomy until the 1980s. The breast is removed along with the lining over the chest muscle and all of the lymph nodes.
- **Simple mastectomy.** Simple, sometimes called total, mastectomy has been the treatment of choice in the late 1980s and 1990s. Generally, only the breast is removed; though, sometimes, one or two lymph nodes may be removed as well.
- **Partial mastectomy.** Partial mastectomy is used to remove the tumor, the lining over the chest muscle underneath the tumor, and a good portion of breast tissue, but not the entire breast. This is a good treatment choice for early stage cancers.
- **Lumpectomy.** Lumpectomy or breast-conserving surgery just removes the tumor and a small amount of tissue surrounding it. Some lymph nodes may be removed as well. This is the most commonly used surgical procedure for the treatment of breast cancer in the early twenty-first century.

Two other surgical procedures are variations on the simple mastectomy. The skin-sparing mastectomy is a new surgical procedure in which the surgeon makes an incision, sometimes called a keyhole incision, around the areola. The tumor and all breast tissue are removed, but the incision is smaller and scarring is minimal. About 90% of the skin is preserved and allows a cosmetic surgeon to perform breast reconstruction at the same time as the mastectomy. The subcutaneous mastectomy, or nipple-sparing mastectomy, preserves the skin and the nipple over the breast.

During a simple mastectomy, the surgeon makes a curved incision along one side of the breast and removes the tumor and all of the breast tissue. A few lymph nodes may be removed. The tumor, breast tissue, and any lymph nodes will be sent to the pathology lab for analysis. If the skin is cancer-free, it is sutured in place or used immediately for breast reconstruction. One or two drains will be put in place to remove fluid from the surgical area. Surgery takes from two to five hours; it is longer with breast reconstruction.

## Breast reconstruction

Breast reconstruction, especially if it is begun at the same time as the simple mastectomy, can minimize the sense of loss that women feel when having a breast removed. Although there may be other smaller surgeries later to complete the breast reconstruction, there will not be a second major operation nor an additional scar.

If there is not enough skin left after the mastectomy, a balloon-type expander is put in place. In subsequent weeks, the expander is filled with larger amounts of saline (salt water) solution. When it has reached the appropriate size, the expander is removed and a permanent breast implant is installed.

If there is enough skin, an implant is installed immediately. In other instances, skin, fat, and muscle are removed from the patient's back or abdomen and repositioned on the chest wall to form a breast.

None of these reconstructions have nipples at first. Nipples are later reconstructed in a separate surgery. Finally, the areola is tattooed in to make the reconstructed breast look natural.

Breast reconstruction does not prevent a potential recurrence of breast cancer.

## Diagnosis/Preparation

If a mammogram has not been performed, it is usually ordered to verify the size of the lump the patient has reported. A biopsy of the suspicious lump

and/or lymph nodes is usually ordered and sent to the pathology lab before surgery is discussed.

When a simple mastectomy has been determined, preoperative tests such as blood work, a chest X-ray, and an **electrocardiogram** may be ordered. Blood-thinning medications such as **aspirin** should be stopped several days before the surgery date. The patient is also asked to refrain from eating or drinking the night before the operation.

At the hospital, the patient will sign a consent form, verifying that the surgeon has explained what the surgery is and what it is for. The patient will also meet with the anesthesiologist to discuss the patient's medical history and determine the choice of anesthesia.

### Aftercare

If the procedure is performed as an **outpatient surgery**, the patient may go home the same day of the surgery. The length of the hospital stay for inpatient mastectomies ranges from one to two days. If breast reconstruction has taken place, the hospital stay may be longer.

The surgical drains will remain in place for five to seven days. Sponge baths will be necessary until the **stitches** are removed, usually in a week to 10 days. It is important to avoid overhead lifting, strenuous sports, and sexual intercourse for three to six weeks. After the surgical drains are removed, stretching exercises may be begun, though some physical therapists may start a patient on shoulder and arm mobility exercises while in the hospital.

Since breast removal is often emotionally traumatic for women, seeking out a support group is often helpful. Women in these groups offer practical advice about matters such as finding well-fitting bras and swimwear, and emotional support because they have been through the same experience.

For women who chose not to have breast reconstruction, it may be necessary to find the proper fitting breast prosthesis. Some are made of cloth, and others are made of silicone, which are created from a mold from the patient's other breast.

In some case, the patient may be required to undergo additional treatments such as radiation, chemotherapy, or hormone therapy.

### Risks

The risks involved with simple mastectomy are the same for any major surgery; however, there may be a need for more extensive surgery once the surgeon examines the tumor, the tissues surrounding it, and the lymph

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

Simple mastectomy is performed by a general surgeon or a gynecological surgeon. If reconstructive breast surgery is to be done, a cosmetic surgeon performs it. Patients undergo simple mastectomies under general anesthesia as an inpatient in a hospital. There is a growing trend, due to reductions in insurance coverage and patient preference, to perform simple mastectomies without reconstructive breast surgery as outpatient procedures.

nodes nearby. A biopsy of the lymph nodes is usually performed during surgery and a determination is made whether to remove them. Simple mastectomy usually has limited impact on range of motion of the arm nearest the breast that is removed, but physical therapy may still be necessary to restore complete movement.

There is also the risk of infection around the incision. When the lymph nodes are removed, lymphedema may also occur. This condition is a result of damage to the lymph system. The arm on the side nearest the affected breast may become swollen. It can either resolve itself or worsen.

As in any surgery, the risk of developing a blood clot after a mastectomy is a serious matter. All hospitals use a variety of techniques to prevent blood clots from forming. It is important for the patient to walk daily when at home.

Finally, there is the risk that not all cancer cells were removed. Further treatment may be necessary.

### Normal results

The breast area will fully heal in three to four weeks. If the patient had breast reconstruction, it may take up to six weeks to recover fully. The patient should be able to participate in all of the activities she has engaged in before surgery. If breast reconstruction is done, the patient should realize that the new breast will not have the sensitivity of a normal breast. In addition, dealing with cancer emotionally may take time, especially if additional treatment is necessary.

### Morbidity and mortality rates

Deaths due to breast cancer have declined by 1.4% each year between 1989 and 1995, and by 3.2% each year thereafter. The largest decreases have been

## QUESTIONS TO ASK THE DOCTOR

- Why is this procedure necessary?
- How big is my tumor?
- Are there other breast-saving or less-invasive procedures for which I might be a candidate?
- What can I expect after surgery?
- Do you work with a cosmetic surgeon?
- Will I have to undergo radiation or chemotherapy after surgery?

among younger women, as a result of cancer education campaigns and early screening, which encourages more women to go to their physicians to be checked.

Research performed between 2000 and 2004 demonstrated that the five-year survival rate for cancers confined to the breast is 98%. For cancers that had spread to areas within the chest region, the rate was 83.5%, and it is only 26.7% for cancers occurring in other parts of the body after breast cancer treatment. The best survival rates were for early-stage tumors.

Two 20-year longitudinal studies concluded in 2002 indicated that the survival rate for patients with modified radical mastectomy (the removal of the entire breast and all lymph nodes) was no different from that of breast-conserving lumpectomy (the removal of the tumor alone). These studies suggest that the removal of the entire breast may not afford greater protection against future cancer than breast-conserving techniques; however, the majority of cancer recurrences happen within the first five years for both those with mastectomies and those with lumpectomies.

### Alternatives

Skin sparing mastectomy, also called nipple sparing mastectomy, is becoming a treatment of choice for women undergoing simple mastectomy. In this procedure, the skin of the breast, the areola, and the nipple are peeled back to remove the breast and its inherent tumor. Biopsies of the skin and nipple areas are performed immediately to assure that they do not have cancer cells in them. Then, a cosmetic surgeon performs a breast reconstruction at the same time as the mastectomy. The breast regains its normal contours once prostheses are inserted. Unfortunately, the nipple will lose its sensitivity and, of course, its function, since all underlying tissue has been removed. If cancer is found near the nipple, this procedure cannot be done.

## Skin grafting

### Definition

Skin grafting is a surgical procedure in which skin or a skin substitute is placed over a burn or non-healing wound.

### Purpose

A skin graft is used to permanently replace damaged or missing skin or to provide a temporary wound covering. This covering is necessary because the skin

Skin grafts may be used in several thicknesses (A). To begin the procedure, a special cement is used on the donor skin area (C). The grafting machine is applied to the area, and sample taken (D). After the graft is stitched to the recipient area, it is covered with nonadherent gauze (E) and a layer of fluffy surgical gauze held in place with sutures (F). (Illustration by GGS Information Services. Cengage Learning, Gale.)

protects the body from fluid loss, aids in temperature regulation, and helps prevent disease-causing bacteria or viruses from entering the body. Skin that is damaged extensively by burns or non-healing wounds can compromise the health and well-being of the patient.

### Demographics

Although anyone can be involved in a fire and need a skin graft, the population groups with a higher risk of fire-related injuries and deaths include:

- children four years old and younger;
- adults 65 years and older;
- African Americans and Native Americans;
- low-income Americans;
- persons living in rural areas; and
- persons living in manufactured homes (trailers) or substandard housing.

### Description

The skin is the largest organ of the human body. It is also known as the integument or integumentary system because it covers the entire outside of the body. The skin consists of two main layers: the outer layer, or epidermis, which lies on and is nourished by the thicker dermis. These two layers are approximately 0.04–0.08 in (1–2 mm) thick. The epidermis consists of an outer layer of dead cells called keratinocytes, which provide a tough protective coating, and several layers of rapidly dividing cells just beneath the keratinocytes. The dermis contains the blood vessels, nerves, sweat glands, hair follicles, and oil glands. The dermis consists mainly of connective tissue, which is largely made up of a protein called collagen. Collagen gives the skin its flexibility and provides structural support. The fibroblasts that make collagen are the main type of cell in the dermis.

Skin varies in thickness in different parts of the body; it is thickest on the palms and soles of the feet, and thinnest on the eyelids. In general, men have thicker skin than women, and adults have thicker skin than children. After age 50, however, the skin begins to grow thinner again as it loses its elastic fibers and some of its fluid content.

#### *Injuries treated with skin grafts*

Skin grafting is sometimes done as part of elective **plastic surgery** procedures, but its most extensive use is in the treatment of burns. For first or second-degree burns, skin grafting is generally not required, as these burns usually heal with little or no scarring. With third-degree burns, however, the skin is destroyed to its full depth, in addition to damage done to underlying

### KEY TERMS

**Allograft**—Tissue that is taken from one person's body and grafted to another person.

**Autograft**—Tissue that is taken from one part of a person's body and transplanted to a different part of the same person.

**Collagen**—A protein that provides structural support for the skin. Collagen is the main component of connective tissue.

**Contracture**—An abnormal persistent shortening of a muscle or the overlying skin at a joint, usually caused by the formation of scar tissue following an injury.

**Débridement**—The removal of foreign matter and dead or damaged tissue from a traumatic or infected wound until healthy tissue is reached.

**Dermatome**—A surgical instrument used to cut thin slices of skin for grafts.

**Dermis**—The underlayer of skin, containing blood vessels, nerves, hair follicles, and oil and sweat glands.

**Epidermis**—The outer layer of skin, consisting of a layer of dead cells that perform a protective function and a second layer of dividing cells.

**Fibroblasts**—A type of cell found in connective tissue; produces collagen.

**Hematoma**—A localized collection of blood in an organ or tissue due to broken blood vessels.

**Integument**—A covering; in medicine, the skin as a covering for the body. The skin is also called the integumentary system.

**Keratinocytes**—Dead cells at the outer surface of the epidermis that form a tough protective layer for the skin. The cells underneath divide to replenish the supply.

**Xenograft**—Tissue that is transplanted from one species to another (e.g., pigs to humans).

tissues. People who suffer third-degree burns often require skin grafting.

Wounds such as third-degree burns must be covered as quickly as possible to prevent infection or loss of fluid. Wounds that are left to heal on their own can contract, often resulting in serious scarring; if the wound is large enough, the scar can actually prevent movement of limbs. Non-healing wounds, such as diabetic ulcers, venous ulcers, or pressure sores, can be

treated with skin grafts to prevent infection and further progression of the wounded area.

### *Types of skin grafts*

The term “graft” by itself commonly refers to either an allograft or an autograft. An autograft is a type of graft that uses skin from another area of the patient’s own body if there is enough undamaged skin available, and if the patient is healthy enough to undergo the additional surgery required. An allograft uses skin obtained from another human being. Donor skin from cadavers is frozen, stored, and available for use as allografts. Skin taken from an animal (usually a pig) is called a xenograft because it comes from a nonhuman species. Allografts and xenografts provide only temporary covering because they are rejected by the patient’s immune system within seven to 10 days. They must then be replaced with an autograft.

**SPLIT-THICKNESS GRAFTS.** The most important part of any skin graft procedure is proper preparation of the wound. Skin grafts will not survive on tissue with a limited blood supply (cartilage or tendons) or tissue that has been damaged by radiation treatment. The patient’s wound must be free of any dead tissue, foreign matter, or bacterial contamination. After the patient has been anesthetized, the surgeon prepares the wound by rinsing it with saline solution or a diluted antiseptic (Betadine) and removes any dead tissue by débridement. In addition, the surgeon stops the flow of blood into the wound by applying pressure, tying off blood vessels, or administering a medication (epinephrine) that causes the blood vessels to constrict.

Following preparation of the wound, the surgeon then harvests the tissue for grafting. A split-thickness skin graft involves the epidermis and a little of the underlying dermis; the donor site usually heals within several days. The surgeon first marks the outline of the wound on the skin of the donor site, enlarging it by 3–5% to allow for tissue shrinkage. The surgeon uses a dermatome (a special instrument for cutting thin slices of tissue) to remove a split-thickness graft from the donor site. The wound must not be too deep if a split-thickness graft is going to be successful, since the blood vessels that will nourish the grafted tissue must come from the dermis of the wound itself. The graft is usually taken from an area that is ordinarily hidden by clothes, such as the buttock or inner thigh, and spread on the bare area to be covered. Gentle pressure from a well-padded dressing is then applied, or a few small sutures used to hold the graft in place. A sterile non-adherent dressing is then applied to the raw donor area for approximately three to five days to protect it from infection.

**FULL-THICKNESS GRAFTS.** Full-thickness skin grafts may be necessary for more severe burn injuries. These grafts involve both layers of the skin. Full-thickness autografts are more complicated than partial-thickness grafts, but provide better contour, more natural color, and less contraction at the grafted site. A flap of skin with underlying muscle and blood supply is transplanted to the area to be grafted. This procedure is used when tissue loss is extensive, such as after open fractures of the lower leg, with significant skin loss and underlying infection. The back and the abdomen are common donor sites for full-thickness grafts. The main disadvantage of full-thickness skin grafts is that the wound at the donor site is larger and requires more careful management. Often, a split-thickness graft must be used to cover the donor site.

A composite skin graft is sometimes used, which consists of combinations of skin and fat, skin and cartilage, or dermis and fat. Composite grafts are used in patients whose injuries require three-dimensional reconstruction. For example, a wedge of ear containing skin and cartilage can be used to repair the nose.

A full-thickness graft is removed from the donor site with a scalpel rather than a dermatome. After the surgeon has cut around the edges of the pattern used to determine the size of the graft, he or she lifts the skin with a special hook and trims off any fatty tissue. The graft is then placed on the wound and secured in place with absorbable sutures.

### **Aftercare**

Once a skin graft has been put in place, it must be maintained carefully even after it has healed. Patients who have grafts on their legs should remain in bed for seven to 10 days with their legs elevated. For several months, the patient should support the graft with an Ace bandage or Jobst stocking. Grafts on other areas of the body should be similarly supported after healing to decrease the amount of contracture.

Grafted skin does not contain sweat or oil glands, and should be lubricated daily for two to three months with mineral oil or another bland oil to prevent drying and cracking.

Aftercare of patients with severe burns typically includes psychological or psychiatric counseling as well as **wound care** and physical rehabilitation, particularly if the patient’s face has been disfigured. The severe pain and lengthy period of recovery involved in burn treatment are often accompanied by anxiety and depression. If the patient’s burns occurred in combat, a transportation disaster, terrorist attack, or other fire involving large numbers of people, he or she is at high

risk of developing post-traumatic stress disorder (PTSD). Anti-anxiety medication may be a helpful adjunct to treatment in these patients. Additionally, because burn patients are at high risk of developing stress ulcers in their gastrointestinal system, with a high rate of bleeding, GI medications that prevent stress ulcers are often given to burn patients.

### Risks

The risks of skin grafting include those inherent in any surgical procedure that involves anesthesia. These include reactions to the medications, breathing problems, bleeding, and infection. In addition, the risks of an allograft procedure include transmission of an infectious disease from the donor.

The tissue for grafting and the recipient site must be as sterile as possible to prevent later infection that could result in failure of the graft. Failure of a graft can result from inadequate preparation of the wound, poor blood flow to the injured area, swelling, or infection. The most common reason for graft failure is the formation of a hematoma, or collection of blood in the injured tissues.

### Normal results

A skin graft should provide significant improvement in the quality of the wound site, and may prevent the serious complications associated with burns or non-healing wounds. Normally, new blood vessels begin growing from the donor area into the transplanted skin within 36 hours. Occasionally, skin grafts are unsuccessful or don't heal well. In these cases, repeat grafting is necessary. Even though the skin graft must be protected from trauma or significant stretching for two to three weeks following split-thickness skin grafting, recovery from surgery is usually rapid. A dressing may be necessary for one to two weeks, depending on the location of the graft. Any **exercise** or activity that stretches the graft or puts it at risk for trauma should be avoided for three to four weeks. A one to two-week hospital stay is most often required in cases of full-thickness grafts, as the recovery period is longer.

### Morbidity and mortality rates

According to the American Burn Association, there are more than 1 million burn injuries in the United States each year that require medical attention. Approximately one-half of these require hospitalization, and roughly 25,000 of those burn patients are admitted to a specialized burn unit. About 4,500 people die from burns each year in the United States.

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

Patients with less severe burns are usually treated in a doctor's office or a hospital emergency room. Patients with any of the following conditions, however, are usually transferred to hospitals with specialized burn units: third-degree burns; partial-thickness burns over 10% of their total body area; electrical or chemical burns; smoke inhalation injuries; or preexisting medical disorders that could complicate management, prolong recovery, or affect mortality. In addition, burned children in hospitals without qualified personnel should be admitted to a hospital with a burn unit. A surgical team that specializes in burn treatment and skin grafts will perform the necessary procedures. The team may include neurosurgeons, ophthalmologists, oral surgeons, thoracic surgeons, psychiatrists, and trauma specialists as well as plastic surgeons and dermatologists.

In the United States, about 500,000 people seek medical treatment for burns every year. About 4,000 people die of their burn injury yearly (including 3,500 due to injuries from residential fires, and 500 due to injuries from fires resulting from a car or airplane crash, and chemical and electrical burns). 40,000 people are admitted to hospitals annually for burn treatment; 25,000 of these are admitted to specialized burn center.

About 38% of all burn unit admissions are for burns covering more than 10% of the patient's total body surface area. 10% of these admissions are for burns exceeding 30% of the patient's total body surface area. 70% of all burn unit admissions are for male patients, and 30% are for female patients. The source of burns breaks down as follows: 46% from fire or flame, 32% from hot water scalding, 8% from hot object contact, 4% from electrical burns, 3% from chemical burns, and 6% other source of burn. The survival rate for patients admitted to specialized burn centers is about 94.4%.

Treatment for severe burns has improved dramatically in the past 20 years. In the early twenty-first century, patients can survive with burns covering up to about 90% of the body, although they often face permanent physical impairment.

### Alternatives

There has been great progress in the development of artificial skin replacement products in the early twenty-first century. Although nothing works as well as the patient's own skin, artificial skin products are important

## QUESTIONS TO ASK THE DOCTOR

- Can you explain the process of skin grafting to me?
- Will I be sent to a hospital with a special burn unit?
- How long will I have to stay in the hospital?
- How long will recovery take?
- When will I be able to resume normal activities?
- What will the injured area look like after grafting?

due to the limitation of available skin for allografting in severely burned patients. Unlike allografts and xenografts, artificial skin replacements are not rejected by the patient's body and actually encourage the generation of new tissue. Artificial skin usually consists of a synthetic epidermis and a collagen-based dermis. The artificial dermis consists of fibers arranged in a lattice that acts as a template for the formation of new tissue. Fibroblasts, blood vessels, nerve fibers, and lymph vessels from surrounding healthy tissue grow into the collagen lattice, which eventually dissolves as these cells and structures build a new dermis. The synthetic epidermis, which acts as a temporary barrier during this process, is eventually replaced with a split-thickness autograft or with an epidermis cultured in the laboratory from the patient's own epithelial cells.

Several artificial skin products are available for burns or non-healing wounds, including Integra<sup>®</sup>, Dermal Regeneration Template<sup>®</sup> (from Integra Life Sciences Technology), Apligraf<sup>®</sup> (Novartis), Transcyte<sup>®</sup> (Advance Tissue Science), and Dermagraft<sup>®</sup>. Researchers have also obtained promising results growing or cultivating the patient's own skin cells in the laboratory. These cultured skin substitutes reduce the need for autografts and can reduce the complications of burn injuries. Laboratory cultivation of skin cells may improve the prognosis for severely burned patients with third-degree burns over 50% of their body. The recovery of these patients has been hindered by the limited availability of uninjured skin from their own bodies for grafting. Skin substitutes may also reduce treatment costs and the length of hospital stays. In addition, other research has demonstrated the possibility of using stem cells collected from bone marrow or blood for use in growing skin grafts.

## Skull x rays

### Definition

Skull X-rays are performed to examine the nose, sinuses, and facial bones. These studies may also be referred to as sinus X-rays. X-ray studies produce films, also known as radiographs, by aiming X-rays

(Illustration by GGS Information Services. Cengage Learning, Gale.)

at soft bones and tissues of the body. X-ray beams are similar to light waves, except their shorter wavelength allows them to penetrate dense substances, producing images and shadows on film.

### Purpose

Doctors may order skull X-rays to aid in the diagnosis of a variety of diseases or injuries.

#### *Sinusitis*

Sinus X-rays may be ordered to confirm a diagnosis of sinusitis, or sinus infection.

#### *Fractures*

A skull X-ray may detect bone fractures resulting from injury or disease. The skull X-ray should clearly show the entire skull, jaw bones, and facial bones.

#### *Tumors*

Skull radiographs may indicate tumors in facial bones, tissues, or sinuses. Tumors may be benign (not cancerous) or malignant (cancerous).

### Other

Birth defects (referred to as congenital anomalies) may be detected on a skull X-ray by changes in bone structure. Abnormal tissues or glands resulting from various conditions or diseases may also be shown on a skull radiograph.

### Description

Skull or sinus X-rays may be performed in a doctor's office that has X-ray equipment and a technologist available. The exam may also be performed in an outpatient radiology facility or a hospital radiology department.

In many instances, particularly for sinus views, the patient will sit upright in a chair, perhaps with the head held stable by a foam vise. A film cassette is located behind the patient. The X-ray tube is in front of the patient and may be moved to allow for different positions and views. A patient may also be asked to move his or her head at various angles and positions.

In some cases, technologists will ask the patient to lie on a table and will place the head and neck at various angles. In routine skull X-rays, as many as five different

(Illustration by GGS Information Services. Cengage Learning, Gale.)

views may be taken to allow a clear picture of various bones and tissues. The length of the test will vary depending on the number of views taken, but in general, it should last about 10 minutes. The technologist will usually ask a patient to wait while the films are being developed to ensure that they are adequate before going to the radiologist.

### Preparation

There is no preparation for the patient prior to arriving at the radiology facility. Patients will be asked to remove jewelry, dentures, or other metal objects that may produce artifacts on the film. The referring doctor or X-ray technologist can answer any questions

regarding the procedure. Any woman who is or may be pregnant should tell the technologist.

### Aftercare

There is no aftercare required following skull or sinus X-ray procedures.

### Risks

There are no common side effects from skull or sinus X-ray. The patient may feel some discomfort in the positioning of the head and neck, but will have no complications. Any X-ray procedure carries minimal radiation risk; and children and pregnant women should

## KEY TERMS

**Radiograph**—The actual picture or film produced by an X-ray study.

**X-ray**—A form of electromagnetic radiation with shorter wavelengths than normal light. X-rays can penetrate most structures.

be protected from radiation exposure to the abdominal or genital areas.

### Normal results

Normal results should indicate sinuses, bones, tissues, and other observed areas are of normal size, shape, and thickness for the patient's age and medical history. Results, whether normal or abnormal, will be provided to the referring doctor in a written report.

Abnormal results may include:

#### *Sinusitis*

Air in sinuses will show up on a radiograph as black, but fluid will be cloudy or white (opaque). This helps the radiologist to identify fluid in the sinuses. In chronic sinusitis, the radiologist may also note thickening or destruction of the bony wall of an infected sinus.

#### *Fractures*

Radiologists may recognize even tiny facial bone fractures as a line of defect.

#### *Tumors*

Tumors may be visible if the bony sinus wall is distorted or destroyed. Abnormal findings may result in follow-up imaging studies.

#### *Other*

Skull X-rays may also detect disorders that show up as changes in bone structure, such as Paget's disease of the bone or acromegaly (a disorder associated with excess growth hormones from the pituitary gland). Areas of calcification, or gathering of calcium deposits, or destruction may indicate a condition such as an infection of bone or bone marrow (osteomyelitis).

## Sling procedure

### Definition

The sling procedure, or suburethral sling procedure, refers to a particular kind of surgery using ancillary material to aid in closure of the urethral sphincter function of the bladder. It is performed as a treatment of severe urinary incontinence. The sling procedure, also known as the suburethral fascial sling or the pubovaginal sling, has many forms due to advances in the types of material used for the sling. Some popular types of sling material are teflon (polytetrafluoroethylene), Gore-Tex®, and rectus fascia (fibrous tissue of the rectum). The surgery can be done through the vagina or the abdomen and some clinicians perform the procedure using a laparoscope—a small instrument that allows surgery through very small incisions in the belly button and above the pubic hairline. The long-term efficacy and durability of the laparoscopic suburethral sling procedure for management of stress incontinence are undetermined. A new technique, the tension-free vaginal tape sling procedure (TVT), has gained popularity in recent years and early research indicates high success rates and few postoperative complications. This procedure is done under local anesthetic and offers new opportunities for treatment of stress incontinence. However, TVT has not been researched for its long-term effects. Finally, there are many surgeons who use the sling procedure for all forms of incontinence.

## Purpose

Incontinence is very common and not fully understood. Generally defined as the involuntary loss of urine, incontinence comes in many forms and has many etiologies. Four established types of incontinence, according to the Agency for Health Care Policy and Research, affect approximately 13 million adults—most of them older women. Actual prevalence may be higher because incontinence is widely under reported and under diagnosed. The four types of incontinence are: stress incontinence, urge incontinence (detrusor overactivity or instability), mixed incontinence, and overflow incontinence. There are also other types of incontinence tied to specific conditions, such as neurogenic bladder in which neurological signals to the bladder are impaired.

Stress incontinence is the most frequently diagnosed form of incontinence and occurs largely with physical activity, laughter and coughing, and sneezing. The inability to hold urine can be due to weakness in the internal and external urinary sphincter or due to a weakened urethra. These two conditions, intrinsic sphincter deficiency (ISD) and urethral hypermobility or genuine stress incontinence (GSI), pertain to the inability of the “gatekeeper” sphincter muscles to stay taut and/or the urethra failing to hold urine under pressure from the abdomen. In women, as the pelvic structures relax due to age, injury, or illness, the uterus prolapses and the urethra becomes hypermobile. This allows the urethra to descend at an angle that permits loss of urine and puts pressure upon the sphincter muscles, both internal and external, allowing the mouth of the bladder to stay open.

Urge incontinence, the other frequent type of incontinence, pertains to overactivity of the sphincter in which the muscle contracts frequently, causing the need to urinate. Stress incontinence is often allied with sphincter overactivity and is often accompanied by urge incontinence.

Severe stress incontinence occurs most frequently in women younger than 60 years old. It is thought to be due to the relaxation of the supporting structures of the pelvis that results from childbirth, obesity, or lack of **exercise**. Some researchers believe that aging, perhaps due to estrogen deficiency, is a major cause of severe urinary incontinence in women, but no link has been found between incontinence and estrogen deficiency. Surgery for stress or mixed incontinence is primarily offered to patients who have failed, are not satisfied with, or are unable to comply with more conservative approaches. It is often performed during other surgeries such as urethra prolapse, cystocele surgery, urethral reconstruction, and **hysterectomy**.

## KEY TERMS

**Intrinsic sphincter deficiency (ISD)**—One of the major factors in stress incontinence. Loss of support of the urethra causes the internal sphincter muscles to be unable to keep the bladder neck closed due to lack of contractive ability.

**Pubovaginal sling**—A general term for a procedure that places a sling around the urethra without the use of tension between the sling and the urethra. The is often referred to as the Tension-Free Vaginal Tape (TVT) procedure.

**Stress incontinence**—Incontinence that occurs when abdominal pressure is placed upon the urethra from movements such as coughing, sneezing, laughter, and exercise.

**Urethral fascial sling**—A support and compression aid to urethral function using auxillary material made of patient or donor tissue to undergird the urethra.

The sling procedure gets its name from the tissue attached under the mid- or proximal urethra and sutured at its ends onto a solid structure like the rectus sheath, pubic bone, or pelvic side walls. The procedure is used in the severest cases of stress incontinence, particularly those that have a concomitant sphincter inadequacy (ISD). The sling supports the urethra as it receives pressure from the abdomen and helps the internal sphincter muscles to keep the urethral opening closed. The procedure is the most popular because it has the highest success rate of all surgical remedies for severe stress incontinence related to sphincter inadequacies in both men and women.

## Demographics

Urinary incontinence (UI) plagues 10–35% of adults and at least half of the million nursing home residents in the United States. Other studies indicate that between 10% and 30% of women experience incontinence during their lifetimes, compared to about 5% of men. One reason that more women than men have incontinent episodes is the relatively shorter urethras of women. Women have urethras of about 2 in (5 cm) and men have urethras of 10 in (25.4 cm). Studies have documented that about 50% of all women have occasional urinary incontinence, and as many as 10% have regular incontinence. Nearly 20% of women over age 75 experience daily urinary incontinence. Incontinence is a major factor in individuals entering long term care facilities. Women at highest risk are those who have given birth

to more than three children and women who were given oxytocin to induce labor. Oxytocin puts more pressure on the pelvic muscles than does ordinary labor. Women who smoke have twice the rate of incontinence, according to one study of 600 women. Those women who do high-impact exercises are at much higher risk for incontinence. According to the medical literature, those at highest risk for urinary leakage are gymnasts, followed by softball, volleyball, and basketball players. Finally, women who have diabetes or are obese have higher rates of incontinence. Women who require sling procedures have often had other surgeries for incontinence, necessitating sling procedure to treat intrinsic sphincter deficiency caused by operative trauma. A rarer cause of stress incontinence in older women is urethral instability. In men, stress incontinence is usually caused by sphincter damage after surgery on the prostate.

### Description

Anti-incontinence surgery is used to address the failure of two parts of female urinary continence: loss of support to the bladder neck or central urethra and intrinsic sphincter deficiency (ISD). The surgery does not restore function to the urethra or to the ability for closure to the sphincter. It replaces the mechanism for continence with supporting and compressive aids. Stabilizing the supporting elements of the urethra (ligaments, fascia, and muscles) was thought for many years to be the most important factor in curing incontinence. Called anatomic or genuine stress urinary incontinence (SUI), retropubic procedures, like the Burch procedure, sought only to restore the urethra to a fixed position. However, it became clear with the high failure rate of these procedures that ISD was present and unless surgery could confer some added compressive ability to the closure of the bladder, SUI would persist.

The urethral sling procedure is effective in the treatment of the severest types of incontinence (Types II and III) by re-establishing the “hammock effect” of the proximal or central point of the urethra during abdominal straining. The surgery involves the placement of a piece of material under the urethra at its arterial or vesical juncture and anchoring it on either side of the pubic bone or to the abdominal wall or vaginal wall. This technique involves the creation of a sling from a strip of tissue from the patient’s own abdominal fascia (fibrous tissue) or from a cadaver. Synthetic slings also are used, but some are prone to break down over time.

The urethral sling procedure is most often performed as open surgery, which involves entering the pelvic area from the abdomen or from the vagina while the patient is under general or regional anesthesia.

Broad-spectrum **antibiotics** are offered intravenously. If the patient is fitted with a urethral catheter, ampicillin and gentamicin are administered instead. The patient is placed in stirrups. Surgery takes place as a 6-to-9-cm by 1.5-cm sling is harvested from rectal tissue and sutured under the urethra at each end within the retropubic space (the area that undergirds the urethra). Synthetic tissue or fascia from a donor may also be used.

The goal of the surgery is to create a compression aid to the urethra. This involves an individualized approach to the tension needed on the sling. While the sling procedure is relatively easy to complete, the issue of tension on the sling is hard to determine and involves the use of tests during surgery for determining the compression effect of the sling on the urethra. Some manual tests are performed or a more sophisticated urodynamic test, like cystourethrography, may determine tension. It is important for the surgeon to test tension during surgery because of the high rate of retention of urine (inability to void) after surgery associated with this procedure and the miscalculation of the required tension.

### Diagnosis/Preparation

Candidates for surgical treatment of incontinence must undergo a full clinical, neurological, and radiographic evaluation before there can be direct analysis of the condition to be treated and the desired outcome. Both urethral and bladder functions are evaluated and there is an attempt to determine the conditions associated with stress incontinence. In many women, incontinence may be due to vaginal prolapse. Stress incontinence can be identified by observation of urine during pelvic examination or by a sitting or standing **stress test** where patients are asked to cough or strain and evidence of leakage is obtained. Gynecologists often use a Q-tip test to determine the angle and change in the position of the urethra during straining. Other tests include subtracted cystometry to measure how much the bladder can hold, how much pressure builds up inside the bladder as it stores urine, and how full it is when the patients feels the urge to urinate.

The frequency of stress incontinence as measured by typical symptoms ranges between 33% and 65%. The frequency of stress incontinence is around 12% when measured or defined by cystometric findings. The ability to distinguish SUI as the cause of incontinence, as opposed to ISD, becomes more complicated; but it is a very important factor in the decision to have surgery. A combination of pelvic examination for urethral hypermobility and leak point pressure as measured by coughing or other abdominal straining

has been shown to be very effective in distinguishing ISD, and identifying the patient who needs surgery.

### Aftercare

IV ketorolac and oral and intravenous pain medication are administered, as are postoperative antibiotics. A general diet is available usually on the evening of surgery. When the patient is able to walk, usually the same day, the urethral catheter is removed. The patient must perform self-catheterization to check urine volume every four hours to protect the urethral wall. If the patient is unwilling to perform catheterization, a tube can be placed suprapubically (in the back of the pubis) for voiding. Catheterization lasts about eight days, with about 98% of patients able to void at three months. Patients are discharged on the second day postoperatively, unless they have had other procedures and need additional recovery time. Patients may not lift heavy objects or engage in strenuous activity for approximately six weeks. Sexual intercourse may be resumed in the fourth week following surgery. Follow-up visits are scheduled for three to four weeks after surgery.

### Risks

Although the sling treatment has a very high success rate, it is also associated with a prolonged period of voiding difficulties, intraoperative bladder or urethra injury, infections associated with screw or staple points, and rejection of sling material from a donor or erosion of synthetic sling material. Patients should not be encouraged to undergo a sling procedure unless the risk of long-term voiding difficulty and the need for intermittent self-catheterization are understood. Fascial slings seem to be associated with the fewest complications for sling procedure treatment. Synthetic slings have a greater risk of having to be removed due to erosion and inflammation.

### Normal results

Regardless of the procedure used, a proportion of patients will remain incontinent. Results vary according to the type of sling procedure used, the type of attachment used for the sling, and the type of material used for the sling. Normal results for the sling procedure overall are recurrent stress incontinence of 3–12% after bladder sling procedures. In general, reported cure rates are lower for second and subsequent surgical procedures. A recent qualitative study published in the *American Journal of Obstetrics and Gynecology* of 57 patients who underwent patient-contributed fascial sling procedures indicates good success with fascial

## WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

The surgery is performed by a urological surgeon who has trained specifically for this procedure. The surgery takes place in a general hospital.

sling procedures. At a median of 42 months after the procedure, the postoperative objective cure rate for stress urinary incontinence was 97%, with 88% of patients indicating that the sling had improved the quality of their lives. Eighty-four percent of patients indicated that the sling relieved their incontinence long term, and 82% of patients stated that they would undergo the surgery again. The study also found that voiding function was a common side effect in 41% of the patients.

### Morbidity and mortality rates

The most common complications of sling procedures are voiding problems (10.4%), new detrusor instability (7–27%), and lower urinary tract damage (3%). Some of the complications depend upon tension issues as well as on the materials used for the sling. There are recent and well designed studies of patient fascia and donor fascia used for slings in five centers with follow-up from 30 to 51 months that report no erosions or vaginal wall complications in any patients. Prolonged retention or voiding issues occurred in 2.3% of patients and de novo or spontaneous urge incontinence developed in 6%. These figures relate only to a large study utilizing patient or donor fascia and one that did not control for other factors like techniques of anchoring. In general, studies of the sling procedure are small and have many variables. There are no long-term studies (over five years) of this most popular procedure.

### Alternatives

Alternatives to anti-incontinent sling procedure surgery depend upon the severity of the incontinence and the type. Severe stress incontinence with intrinsic sphincter deficiency can benefit from bulking agents for the urethra to increase compression, as well as external devices like a pessary that is placed in the vagina and holds up the bladder to prevent leakage. Urethral inserts can be placed in the urethra until it is time to use the bathroom. The patient learns to put the insertion in and take it out as needed. There are also

## QUESTIONS TO ASK THE DOCTOR

- Do I have a urethral closure problem as a part of my incontinence?
- How many sling procedures have you performed?
- How soon will I be able to tell if I am going to have urine retention difficulties?
- If this surgery does not work, are there other procedures that will allow me a better quality of life?
- Is patient satisfaction a formal part of your evaluation of the success of the procedure you use?
- What type of material do you use for the sling and why do you choose this material?

urine seals that are small foam pads inserted in garments. Milder forms of incontinence can benefit from an assessment of medication usage, pelvic muscle exercises, bladder retraining, weight loss, and certain devices that stimulate the muscles around the urethra to strengthen them. For mild urethral mobility, procedures for tacking or stabilizing the urethra at the neck called Needle Neck Suspension, as well as procedures to hold the urethra in place with sutures, like the Burch method, are alternative forms of surgery.

## Smoking cessation

### Definition

Smoking cessation means “quitting smoking,” or “withdrawal from nicotine.” Tobacco is highly addictive, therefore, quitting the habit often involves irritability, headache, mood swings, and cravings associated with the sudden cessation or reduction of tobacco use by a nicotine-dependent individual.

### Purpose

There are many good reasons to stop smoking; one of them is that smoking cessation may speed post-surgery recovery. Smoking cessation helps a person heal and recover faster, especially in the incision area, or if the surgery involved any bones. Research shows that patients who underwent hip and knee replacements, or surgery on other bone joints, healed better and recovered more quickly if they had quit or cut down their tobacco intake several weeks before the operation. Smoking weakens the bone mineral that keeps the skeleton strong and undermines tissue and vessel health. One study suggested that even quitting tobacco for a few days could improve tissue blood flow and oxygenation, and might have a positive effect on wound healing. If a patient has had a history of heart problems, his chances of having a second heart attack will be lowered. Quitting may also reduce wound complications, and lower the risk of cardiovascular trouble after surgery. If surgery was performed to remove cancerous tumors, quitting will reduce the

## KEY TERMS

**Addiction**—Compulsive, overwhelming involvement with a specific activity. The activity may be smoking, gambling, alcohol, or may involve the use of almost any substance, such as a drug.

**Appetite suppressant**—To decrease the appetite.

**Constrict**—To squeeze tightly, compress, draw together.

**Convulsion**—To shake or effect with spasms; to agitate or disturb violently.

**Depressant**—A drug or other substance that soothes or lessens tension of the muscles or nerves.

**Detoxification**—To remove a poison or toxin or the effect of such a harmful substance; to free from an intoxicating or addictive substance in the body or from dependence on or addiction to a harmful substance.

**Endorphins**—Any of a group of proteins with analgesic properties that occur naturally in the brain.

**Gestational age**—The length of time of growth and development of the young in the mother's womb.

**Metabolism**—The sum of all the chemical processes that occur in living organisms; the rate at which the body consumes energy.

**Nicotine**—A poisonous, oily alkaloid in tobacco.

**Oxygenation**—To supply with oxygen.

**Paraphernalia**—Articles of equipment or accessory items.

**Premature**—Happening early or occurring before the usual time.

**Psychoactive**—Affecting the mind or behavior.

**Respiratory infections**—Infections that relate to or affect respiration or breathing.

**Smoking cessation**—The act of quitting smoking or withdrawal from nicotine.

**Stimulant**—A drug or other substance that increases the rate of activity of a body system.

**Tremor**—A trembling, quivering, or shaking.

**Withdrawal**—Stopping of administration or use of a drug; the syndrome of sometimes painful physical and psychological symptoms that follow the discontinuance.

risk of a second tumor, especially if cancer in the lung, head, or neck has been successfully treated.

### Description

Quitting smoking is one of the best things a person can do to increase their life expectancy. On average, male smokers who quit at 35 years old can be expected to live to be 76 years old instead of 69 years if they were still smoking. Women who quit would live to be 80 years old instead of 74 years.

### *Effects of smoking on the body*

Nicotine acts as both a stimulant and a depressant on the body. Saliva and bronchial secretions increase along with bowel tone. Some inexperienced smokers may experience tremors or even convulsions with high doses of nicotine because of the stimulation of the central nervous system. The respiratory muscles are then depressed following stimulation.

Nicotine causes arousal as well as relaxation from stressful situations. Tobacco use increases the heart rate about 10–20 beats per minute; and because it constricts the blood vessels, it increases the blood pressure reading by 5–10 mm Hg.

Sweating, nausea, and diarrhea may also increase because of the effects of nicotine upon the central nervous system. Hormonal activities of the body are also affected. Nicotine elevates the blood glucose levels and increases insulin production; it can also lead to blood clots. Smoking does have some positive effects on the body by stimulating memory and alertness, and enhancing cognitive skills that require speed, reaction time, vigilance, and work performance. Smoking tends to alleviate boredom and reduce stress as well as reduce aggressive responses to stressful events because of its mood-altering ability. It also acts as an appetite suppressant, specifically decreasing the appetite for simple carbohydrates (sweets) and inhibiting the efficiency with which food is metabolized. The fear of weight gain prevents some people from quitting smoking. The addictive effects of tobacco have been well documented. It is considered mood- and behavior-altering, psychoactive, and prone to abuse. Tobacco's addictive potential is believed to be comparable to the addictive potentials of alcohol, cocaine, and morphine.

### *Health problems associated with smoking*

In general, chronic use of nicotine may cause an acceleration of coronary artery disease, hypertension,

reproductive disturbances, esophageal reflux, peptic ulcer disease, fetal illnesses and **death**, and delayed wound healing. The smoker is at greater risk of developing cancer (especially in the lung, mouth, larynx, esophagus, bladder, kidney, pancreas, and cervix); heart attacks and strokes; and chronic lung disease. Using tobacco during pregnancy increases the risk of miscarriage, intrauterine growth retardation (resulting in the birth of an infant small for gestational age), and the infant's risk for sudden infant death syndrome.

The specific health risks of tobacco use include: nicotine addiction, lung disease, lung cancer, emphysema, chronic bronchitis, coronary artery disease and angina, heart attack, atherosclerotic and peripheral vascular disease, aneurysms, hypertension, blood clots, strokes, oral/tooth/gum diseases including oral cancer, and cancer in the kidney, bladder, and pancreas. Nicotine is also associated with decreased senses of taste and smell. During pregnancy, nicotine may cause increased fetal death, premature labor, low birth weight infants, and sudden infant death syndrome.

Smoking is also increasingly harmful to a person's social acceptability. According to the National Institute on Drug Abuse (NIDA), students at the high school and college levels in the early twenty-first century are increasingly disapproving of smoking. In just one year, disapproval of smoking among high school seniors increased from 76.2% in 2004 to 79.8% in 2005. For young adults, smoking complicates finding housing, as many landlords will not rent to smokers and many potential roommates do not want to share their apartment with a smoker.

Nonsmokers who are regularly exposed to secondhand smoke also may experience specific health risks including:

- Increased risk of lung cancer.
- An increased frequency of respiratory infections in infants and children (e.g. bronchitis and pneumonia), asthma, and decreases in lung function as the lungs mature.
- Acute, sudden, and occasionally severe reactions including eye, nose, throat, and lower respiratory tract symptoms.

The specific health risks for smokeless tobacco users include many of the diseases of smokers, as well as a 50-fold greater risk for oral cancer with long-term or regular use.

In diabetics taking medication for high blood pressure, it has been reported that smoking may increase the risk of kidney disease and/or kidney failure.

### *Making a plan to quit*

Long lead times for elective procedures like joint operations offer a good opportunity for doctors to encourage their patients to quit smoking, but only the smoker has the power to stop smoking. Before a smoker decides to quit, he should make sure he wants to quit smoking for himself, and not for other people. The following are some suggestions the smoker may want to consider:

- The first step is to set a quit date. Women should set their quit date to begin at the end of their period for best results.
- Make a written list of why you want to quit smoking.
- Consider using an aid to help you quit, which can be the patch, nicotine gum, Zyban, nicotine spray, soft laser therapy, nasal inhaler, or some other method. If you plan to use Zyban, set your quit date for one week after you begin to use it.
- Smoke only in certain places, preferably outdoors.
- Switch to a brand of cigarettes that you don't like.
- Buy a piggy bank or an attractive box or jar and put the money in it that you would ordinarily spend on cigarettes. At an average cost of \$5 per pack, the money in your savings bank will quickly add up.
- Do not buy cigarettes by the carton.
- Cut coffee consumption in half. You will not need to give it up.
- Practice putting off lighting up when the urge strikes.
- Go for a walk every day or begin an exercise program.
- Stock up on non-fattening safe snacks to help with weight control after quitting.
- Enlist the support of family and friends.
- Clean and put away all ashtrays the day before quitting.

Smokers who are trying to quit should remind themselves that they are doing the smartest thing they have ever done. Because of the preparation for smoking cessation, the smoker won't be surprised by or fearful of quitting. The quitter will be willing to do what's necessary, even though it won't be easy. Remember, this will likely add years to the lifespan. The quitting smoker should be prepared to spend more time with nonsmoking friends, if other smokers don't support the attempt to quit.

Since hospitals are smoke-free environments, if a smoking patient is in the hospital for **elective surgery**, it may be a good opportunity to quit smoking. It might be best to set the quit date around the time of the surgery and let the attending doctor know. As the smoker takes the first step, professional hospital staff will be there to give the support and help needed.

Medical staff can start the patient on nicotine replacement therapy to help control the cravings and increase the chances of quitting permanently.

### *Methods of quitting*

Cold turkey, or an abrupt cessation of nicotine, is one way to stop smoking. Cold turkey can provide cost savings because paraphernalia and smoking cessation aids are not required; however, not everyone can stop this way as tremendous willpower is needed.

Laser therapy is an entirely safe and pain free form of acupuncture that has been in use since the 1980s. Using a painless soft laser beam instead of needles the laser beam is applied to specific energy points on the body, stimulating production of endorphins. These natural body chemicals produce a calming, relaxing effect. It is the sudden drop in endorphin levels that leads to withdrawal symptoms and physical cravings when a person stops smoking. Laser treatment not only helps relieve these cravings, but helps with stress reduction and lung detoxification. Some studies indicate that laser therapy is the most effective method of smoking cessation, with an extraordinarily high success rate.

Acupuncture—small needles or springs are inserted into the skin—is another aid in smoking cessation. The needles or springs are sometimes left in the ears and touched lightly by the patient between visits.

Some smokers find hypnosis particularly useful, especially if there is any kind of mental conflict, such as phobias, panic attacks, or weight control. As a smoker struggles to stop smoking, the conscious mind, deciding to quit, battles the inner mind, which is governed by habit and body chemistry. Hypnosis, by talking directly to the inner mind, can help to resolve that inner battle.

Some people are helped to quit smoking by psychotherapy. As of 2007, cognitive behavioral therapy, or CBT, is considered the most effective form of psychotherapy for smoking cessation. A research team at Yale University reported in the fall of 2007 that CBT was more effective than brief behavioral interventions in helping adolescent smokers stay in a smoking cessation program as well as actually quitting smoking.

Aversion techniques attempt to make smoking seem unpleasant. This technique reminds the person of the distasteful aspects of smoking, such as the smell, dirty ashtrays, coughing, the high cost, and health issues. The most common technique prescribed by psychologists for “thought stopping”—stopping unwanted thoughts—is to wear a rubber band around the wrist. Every time there is an unwanted thought (a craving to smoke) the band is supposed to be pulled so that it hurts. The

thought then becomes associated with pain and gradually neutralized.

Rapid smoking is a technique in which smoking times are strictly scheduled once a day for the first three days after quitting. Phrases are repeated such as “smoking irritates my throat” or “smoking burns my lips and tongue.” This technique causes over-smoking in a way that makes the taste and sensations associated with smoking very unpleasant.

There are special mouthwashes available, which, when used before smoking, alter the taste, giving cigarettes a very unpleasant taste. The intention is to create a link in the smoker’s mind between cigarettes and a bad taste in the mouth.

Smoking cessation aids wean a person off nicotine slowly, and the nicotine can be delivered where it does the least bodily harm. Unlike cigarettes, these aids do not introduce other harmful poisons to the body. They can be used for a short period of time; however, nicotine from any source (smoking, nicotine gum, or the nicotine patch) can make some health problems worse. These include heart or circulation problems, irregular heartbeat, chest pain, high blood pressure, overactive thyroid, stomach ulcers, or diabetes.

The four main brands of the patch are Nicotrol, Nicoderm, Prostep, and Habitrol. All four transmit low doses of nicotine to the body throughout the day. The patch comes in varying strengths ranging from 7 mg to 21 mg. The patch must be prescribed and used under a physician’s care. Package instructions must be followed carefully. Other smoking cessation programs or materials should be used while using the patch.

Nicorette gum allows the nicotine to be absorbed through the membrane of the mouth between the cheek and gums. Past smoking habits determine the right strength to choose. The gum should be chewed slowly.

The nicotine nasal spray reduces cravings and withdrawal symptoms, allowing smokers to cut back slowly. The nasal spray acts quickly to stop the cravings, as it is rapidly absorbed through the nasal membranes. One of the drawbacks is a risk of addiction to the spray.

The nicotine inhaler uses a plastic mouthpiece with a nicotine plug, delivering nicotine to the mucous membranes of the mouth. It provides nicotine at about one-third the nicotine level of cigarettes.

Bupropion hydrochloride, sold under the trade name Zyban, is an oral medication that is making an impact in the fight to help smokers quit. It is a treatment for nicotine dependence. Another new medication,

approved by the Food and Drug Administration (FDA) in 2006, is varenicline tartrate, sold under the trade name Chantix. Chantix is thought to work by affecting parts of the brain affected by nicotine in two ways: by providing some nicotine effects to ease withdrawal symptoms and by blocking the effects of nicotine from cigarettes if the patient resumes smoking. In November 2007, however, the FDA issued a warning regarding mood changes reported in persons taking Chantix. The drug is still considered safe, but anyone taking it in order to stop smoking should contact their doctor at once if they feel depressed or notice other sudden mood changes.

The nicotine lozenge is another smoking cessation aid recently added to the growing list of tools to combat nicotine withdrawal.

As of 2007, scientists are researching the possibility of developing medications that inhibit the function of CYP2A6, an enzyme that makes people more susceptible to nicotine addiction. Some people have a genetic variant that decreases the amount of CYP2A6 in the body, which is thought to protect these individuals against nicotine addiction. Thus medications that lower the amount of this enzyme might offer a new approach to smoking cessation.

### *Withdrawal symptoms*

Generally, the longer one has smoked and the greater the number of cigarettes (and nicotine) consumed, the more likely it is that withdrawal symptoms will occur and the more severe they are likely to be. When a smoker switches from regular to low-nicotine cigarettes or significantly cuts back smoking, a milder form of nicotine withdrawal involving some or all of these symptoms can occur.

These are some of the withdrawal symptoms that most former smokers experience in the beginning of their new smoke-free life:

- dry mouth;
- mood swings;
- irritability;
- feelings of depression;
- gas in the digestive tract;
- tension;
- sleeplessness or sleeping too much;
- difficulty in concentration;
- intense cravings for a cigarette;
- increased appetite and weight gain; and
- headaches.

These side effects are all temporary conditions that will probably subside in a short time for most

people. These symptoms can last from one to three weeks and are strongest during the first week after quitting. Drinking plenty of water during the first week can help detoxify the body and shorten the duration of the withdrawal symptoms. A positive attitude, drive, commitment, and a willingness to get help from health care professionals and support groups will help a smoker kick the habit.

Researchers from the University of California San Diego strongly suggest that any of the above cessation aids should be used in combination with other types of smoking cessation help, such as counseling and/or support programs. These products are not designed to help with the behavioral aspects of smoking, but only the cravings associated with them. Counseling and support groups can offer tips on coping with difficult situations that can trigger the urge to smoke.

### **Even a new heart can't break a bad habit**

Why do some people who have heart transplants continue to smoke? In a three-year study at the University of Pittsburgh of 202 heart transplant recipients, 71% of the recipients were smokers before surgery. The overall rate of post-transplant smoking was 27%. All but one of the smokers resumed the smoking habit they had before the transplant. The biggest reason for resuming smoking was addiction to nicotine. Smoking is a complex behavior, involving social interactions, visual cues, and other factors. Those who smoked until less than six months before the transplant were much more likely to resume smoking early and to smoke more. One of the major causes of early relapse was because of depression and anxiety within two months after the transplant. Another strong predictor of relapse was having a caretaker who smoked. The knowledge of these risk factors could help develop strategies for identifying those in greatest need of early intervention. According to European studies, the five-year survival rate for post-transplant smokers is 37%, compared to 80% for nonsmoking recipients. Smokers can develop inoperable lung cancers within five years after a transplant, thus resulting in a shorter survival rate. There is an alarming incidence of head and neck cancers in transplant recipients who resume smoking.

Overall, there is a 90% relapse rate in the general population; however, the more times a smoker tries to quit, the greater the chance of success with each new try.

## Snoring surgery

### Definition

Snoring is defined as noisy or rough breathing during sleep, caused by vibration of loose tissue in the upper airway. Surgical treatments for snoring include several different techniques for removing tissue from the back of the patient's throat, reshaping the nasal passages or jaw, or preventing the tongue from blocking the airway during sleep.

### Purpose

The purpose of snoring surgery is to improve or eliminate the medical and social consequences of heavy snoring. Most insurance companies, however, regard surgical treatment of snoring as essentially a cosmetic procedure—which means that patients must cover its expenses themselves. The major exception is surgery to correct a deviated septum or other obstruction in the nose, on the grounds that nasal surgery generally improves the patient's breathing during the day as well as at night.

### Snoring as a medical problem

The connection between heavy snoring, breathing disorders, and other health problems is a relatively recent discovery. Obstructive sleep apnea (OSA) is a breathing disorder that was first identified in 1965. OSA is marked by brief stoppages in breathing during sleep resulting from partial blockage of the airway. A person with OSA may stop breathing temporarily as often as 20–30 times per hour. He or she usually snores or makes choking and gasping sounds between these episodes. The person is not refreshed by nighttime sleep and may suffer from morning headaches as well as daytime sleepiness. He or she may be misdiagnosed

## KEY TERMS

**Continuous positive airway pressure (CPAP)**—A ventilation device that blows a gentle stream of air into the nose during sleep to keep the airway open.

**Deviated septum**—An abnormal configuration of the cartilage that divides the two sides of the nose. It can cause breathing problems if left uncorrected.

**Injection snoreplasty**—A technique for reducing snoring by injecting a chemical that forms scar tissue near the base of the uvula, helping to anchor it and reduce its fluttering or vibrating during sleep.

**Obstructive sleep apnea (OSA)**—A potentially life-threatening condition characterized by episodes of breathing cessation during sleep alternating with snoring or disordered breathing. The low levels of oxygen in the blood of patients with OSA may eventually cause heart problems or stroke.

**Palate**—The roof of the mouth.

**Polysomnography**—A test administered in a sleep laboratory to analyze heart rate, blood circulation,

muscle movement, brain waves, and breathing patterns during sleep.

**Primary snoring**—Simple snoring; snoring that is not interrupted by episodes of breathing cessation.

**Somnoplasty**—A technique that uses radiofrequency signals to heat a thin needle inserted into the tissues of the soft palate. The heat from the needle shrinks the tissues, thus enlarging the patient's airway. Somnoplasty is also known as radiofrequency volumetric tissue reduction (RFVTR).

**Uvula**—A triangular piece of tissue that hangs from the roof of the mouth above the back of the tongue. Primary snoring is often associated with fluttering or vibrating of the uvula during sleep.

**Uvulopalatopharyngoplasty (UPPP)**—An operation to remove the tonsils and other excess tissue at the back of the throat to prevent it from closing the airway during sleep.

as suffering from clinical depression when the real problem is physical tiredness. In addition, the high levels of carbon dioxide that build up in the blood when a person is not breathing normally may eventually lead to high blood pressure, irregular heartbeat, heart attacks, and stroke. In children, heavy snoring appears to be a major risk factor for attention-deficit/hyperactivity disorder.

Although people with OSA snore, not everyone who snores has OSA. It is thought that OSA affects about 4% of middle-aged males and 2% of middle-aged females. Most adults who snore have what is called primary snoring, which means that the loud sounds produced in the upper airway during sleep are *not* interrupted by episodes of breathing cessation. Other terms for primary snoring are simple snoring, benign snoring, rhythmical snoring, continuous snoring, and socially unacceptable snoring (SUS). Although primary snoring is not associated with severe disorders to the same extent as OSA, it has been shown to have some negative consequences for health, including such things as chronic daily headaches.

### *Snoring as a social problem*

As the term SUS suggests, primary snoring can cause the same social problems for a person as does snoring associated with OSA. People who snore heavily often keep other family members, roommates, or

even neighbors from getting a good night's sleep, which leads to considerable anger and resentment. Studies have found that the nonsnoring partner or roommate loses an average of an hour's sleep each night. According to Dr. Kingman Strohl, head of a sleep disorders program in a Veterans Administration hospital, even the average volume of snoring (60 decibels or dB) is as loud as normal speech. Some people, however, snore around 80–82 dB, the sound level of a loud yell; a few have been recorded as reaching 90 dB, the sound level of loud rock music. One study found that 80% of people married to heavy snorers end up sleeping in separate rooms. A group of Swedish researchers reported that heavy snoring has the same level of negative effects on quality of life among adult males as high blood pressure, chronic obstructive pulmonary disease, heart disease, and similar chronic medical conditions.

### *Risk factors for snoring*

Some people are at higher risk of developing problem snoring than others. Risk factors in addition to sex and age include:

- Genetic factors. The size and shape of the uvula, soft palate, tonsils, and other parts of the airway are largely determined by heredity.
- Family history of heavy snoring.

- Obesity. Severe overweight increases a person's risk of developing OSA.
- Lack of exercise. Physical activity helps to keep the muscles of the throat firm and strong as well as the larger muscles of the body.
- Heavy consumption of alcohol and tobacco.
- A history of frequent upper respiratory infections or allergies.
- Trauma to the nose, face, or throat.

## Demographics

Snoring is a commonplace problem in the general population in North America. About 19% to 37% of all Americans snore, and more than half of all middle-aged men snore. Men are more affected because of the architecture of their throat, and because of hormonal patterns and how those hormones affect fat distribution and the muscles of the upper airway. About 12% of children over the age of five are reported to snore frequently and loudly. Among adults, 45% snore occasionally, while 25% snore almost every night. The problem usually grows worse as people age; 50% of people over age 65 are habitual snorers.

Problem snoring is worse among males than among females in all age brackets. With regard to racial and ethnic differences, a sleep research study published in 2003 reported that frequent snoring is more common (in the United States) among African American women, Hispanic women, and Hispanic men than their Caucasian counterparts, even after adjusting for weight and body mass index (BMI). African American, Native American, and Asian American males have the same rates of snoring as Caucasian males. Further research is needed to determine whether these differences are related to variations in the rates and types of health problems in these respective groups.

According to international researchers, heavy snoring appears to be more common in persons of Asian origin than in persons of Middle Eastern, European, or African origin.

## Description

With the exception of UPPP, all of the surgical treatments for snoring described in this section are outpatient or office-based procedures.

### *Uvulopalatopharyngoplasty (UPPP)*

Uvulopalatopharyngoplasty, or UPPP, is the oldest and most invasive surgical treatment for snoring. It was first performed in 1982 by a Japanese surgeon named S. Fujita. UPPP requires **general anesthesia**, one to two

nights of inpatient care in a hospital, and a minimum of two weeks of recovery afterward. In a uvulopalatopharyngoplasty, the surgeon resects (removes) the patient's tonsils, part of the soft palate, and the uvula. The procedure works by enlarging the airway and removing some of the soft tissue that vibrates when the patient snores. It is not effective in treating snoring caused by obstructions at the base of the tongue.

UPPP has several drawbacks in addition to its cost and lengthy recovery period. It can result in major complications, including severe bleeding due to removal of the tonsils as well as airway obstruction. In addition, the results may not be permanent; between 50% and 70% of patients who have been treated with UPPP report that short-term improvements in snoring do not last longer than a year.

### *Laser-assisted uvulopalatoplasty*

Laser-assisted uvulopalatoplasty, or LAUP, is an outpatient surgical treatment for snoring in which a carbon dioxide laser is used to vaporize part of the uvula, a small triangular piece of tissue that hangs from the soft palate above the back of the tongue. The patient is seated upright in a comfortable chair in the doctor's office. The doctor first sprays a local anesthetic—usually lidocaine—over the back of the patient's throat, covering the patient's soft palate, tonsils, and uvula. The second step is the injection of more anesthetic into the muscle tissue in the uvula. After waiting for the anesthetic to take effect, the surgeon uses a carbon dioxide laser to make two vertical incisions in the soft palate on either side of the uvula. A third incision is used to remove the tip of the uvula. The surgeon also usually removes part of the soft palate itself. The total procedure takes about half an hour.

LAUP is typically performed as a series of three to five separate treatments. Additional treatment sessions, if needed, are spaced four to eight weeks apart.

LAUP was developed in the late 1980s by Dr. Yves-Victor Kamami, a French surgeon whose first article on the technique was published in 1990. Kamami claimed a high rate of success for LAUP in treating OSA as well as snoring. The procedure has become controversial because other surgeons found it less effective than the first reports indicated, and also because most patients suffer considerable pain for about two weeks after surgery. Although some surgeons report a success rate as high as 85% in treating snoring with LAUP, the effectiveness of the procedure is highly dependent on the surgeon's experience and ability.

### *Somnoplasty*

Somnoplasty, or radiofrequency volumetric tissue reduction (RFVTR) is a newer technique in which the surgeon uses a thin needle connected to a source of radiofrequency signals to shrink the tissues in the soft palate, throat, or tongue. It was approved by the U.S. Food and Drug Administration (FDA) for the treatment of snoring in 1997. The needle is inserted beneath the surface layer of cells and heated to a temperature between 158°F and 176°F (70° and 80°C). The upper layer of cells is unaffected, but the heated tissue is destroyed and gradually reabsorbed by the body over the next four to six weeks. Somnoplasty stiffens the remaining layers of tissue as well as reducing the total volume of tissue. Some patients require a second treatment, but most find that their snoring is significantly improved after only one. The procedure takes about 30 minutes and is performed under **local anesthesia**.

Somnoplasty appears to have a higher success rate (about 85%) than LAUP and is considerably less painful. Most patients report two to three days of mild swelling after somnoplasty compared to two weeks of considerable discomfort for LAUP.

### *Tongue suspension procedure*

The tongue suspension procedure, which is also known as the Repose<sup>TM</sup> system, is a minimally invasive surgical treatment for snoring that stabilizes the base of the tongue during sleep, preventing it from falling backward and obstructing the airway. The Repose system was approved by the FDA in 1998. It consists of a titanium screw inserted into the lower jaw on the floor of the mouth and a suture passed through the base of the tongue that is then attached to the screw. The attachment holds the tongue forward during sleep.

The Repose system is done as an outpatient procedure under total anesthesia. It takes about 15–20 minutes to complete. The advantages of the tongue suspension procedure include the fact that it is reversible, since no incision is made; and that it can be combined with UPPP, LAUP, or a **tonsillectomy**. Its disadvantages include its relatively long healing time (one to two weeks) and the fact that it appears to be more effective in treating OSA than primary snoring. One team of American and Israeli researchers who conducted a multicenter trial concluded that the tongue suspension procedure requires further evaluation.

### *Injection snoreplasty*

Injection snoreplasty was developed by a team of Army physicians at Walter Reed Hospital and introduced to other ear, nose and throat specialists at a

professional conference in 2000. In injection snoreplasty, the surgeon gives the patient a local anesthetic and then injects a hardening agent known as sodium tetradecyl sulfate underneath the skin of the roof of the mouth just in front of the uvula. The chemical, which is also used in sclerotherapy, creates a blister that hardens into scar tissue. The scar tissue pulls the uvula forward, reducing the vibration or flutter that causes snoring.

Preliminary research indicates that injection snoreplasty is safe, has a higher rate of success than LAUP (about 92%), and is also less painful. Most patients need only one treatment, and can manage the discomfort the next day with a mild **aspirin** substitute and throat spray. The primary drawback of injection snoreplasty is that it treats only tissues in the area of the uvula. Snoring caused by tissue vibrations elsewhere in the throat requires another form of treatment. Injection snoreplasty costs about \$500 per treatment.

## **Diagnosis/Preparation**

### *Diagnosis*

The most important task in diagnosing a patient's snoring is to distinguish between primary snoring and obstructive sleep apnea. The reason for care in the diagnosis is that surgical treatment without the recommended tests for OSA can complicate later diagnosis of the disorder.

The sounds made when a person snores have a number of different physical causes. Snoring noises may result from one or more of the following:

- An unusually long soft palate and uvula. These structures narrow the airway between the nose and the throat. They act like noisy flutter valves when the person breathes in and out during sleep.
- Too much tissue in the throat. Large tonsils and adenoids can cause snoring, which is one reason why tonsillectomies are sometimes recommended to treat heavy snoring in children.
- Nasal congestion. When a person's nose is stuffy, their attempts to breathe create a partial vacuum in the throat that pulls the softer tissues of the throat together. This suction can also produce a snoring noise. Nasal congestion helps to explain why some people snore only when they have a cold or during pollen season.
- Anatomical deformations of the nose. People who have had their noses or cheekbones fractured or who have a deviated septum are more likely to snore, because their nasal passages develop a twisted or crooked shape and vibrate as air passes through them.

- **Sleeping position.** People are more likely to snore when they are lying on the back because the force of gravity draws the tongue and soft tissues in the throat backward and downward, blocking the airway.
- **Obesity.** Obesity adds to the weight of the tissues in the neck, which can cause partial blockage of the airway during sleep.
- **Use of alcohol, sleeping medications, or tranquilizers.** These substances relax the throat muscles, which may become soft or limp enough to partially close the airway.

Because snoring may be related to lifestyle factors, upper respiratory infections, seasonal allergies, and sleeping habits as well as the anatomy of the person's airway, a complete medical history is the first step in determining suitable treatments. In some cases the patient may have been referred by his or her dentist on the basis of findings during a dental procedure. A primary care doctor can take a history and perform a basic examination of the patient's nose and throat. In addition, the primary care doctor may give the patient one or more short questionnaires to evaluate the severity of daytime sleepiness and other problems related to snoring. The test most commonly used is the Epworth Sleepiness Scale (ESS), which was developed by an Australian physician, Dr. Murray Johns, in 1991. The ESS lists eight situations (reading, watching TV, etc.) and asks the patient to rate his or her chances of dozing off in each situation on a four-point scale (0–3, with 3 representing a high chance of falling asleep). A score of 6 or lower indicates that the person is getting enough sleep; a score higher than 9 is a danger sign. The ESS is often used to measure the effectiveness of various treatments for snoring as well as to evaluate patients prior to surgery.

The next stage in the differential diagnosis of snoring problems is a detailed examination of the patient's airway by an otolaryngologist, who is a physician who specializes in diagnosing and treating disorders involving the nose and throat. The American Sleep Apnea Association (ASAA) maintains that no one should consider surgery for snoring until their airway has been examined by a specialist. The otolaryngologist will be able to determine whether the size and shape of the patient's uvula, soft palate, tonsils and adenoids, nasal cartilage, and throat muscles are contributing factors, and to advise the patient on specific procedures. It may be necessary for the patient to undergo more than one type of treatment for snoring, as some surgical procedures correct only one or two structures in the nose or throat.

A complete airway examination consists of an external examination of the patient's face and neck; an endoscopic examination of the nasal passages and throat; the use of a laryngeal mirror or magnifying laryngoscope to study the lower portions of the throat; and various imaging studies. The otolaryngologist may use a nasopharyngoscope, which allows for evaluation of obstructions below the palate and the tongue, and may be performed with the patient either awake or asleep. The nasopharyngoscope is a flexible fiberoptic device that is introduced into the airway through the patient's nose. Other imaging studies that may be done include acoustic reflection, computed tomography (CT) scans, or **magnetic resonance imaging (MRI)**.

In addition to the airway examination, patients considering surgical treatment for snoring must make an appointment for sleep testing in a specialized laboratory. The American Academy of Sleep Medicine recommends this step in order to exclude the possibility that the patient has obstructive sleep apnea. Sleep testing consists of an overnight stay in a special sleep laboratory. Before the patient goes to sleep, he or she will be connected to a polysomnograph, which is an instrument that monitors the patient's breathing, heart rate, temperature, muscle movements, airflow, body position, and other measurements that are needed to evaluate the cause(s) of sleep disorders. A technician records the data in a separate room. As of 2003, some companies are developing portable polysomnographs that allow patients to connect the device to a computer in their home and transmit the data to the sleep center over an Internet connection.

### Preparation

Apart from the extensive diagnostic testing that is recommended, preparation for outpatient snoring surgery is usually limited to taking a mild sedative before the procedure. Preparation for UPPP requires a **physical examination**, EKG, blood tests, and a preoperation interview with the anesthesiologist to evaluate the patient's fitness for general anesthesia.

### Aftercare

Aftercare following outpatient snoring surgery consists primarily of medication for throat discomfort, particularly when swallowing. The patient can resume normal work and other activities the same day as the procedure, and speaking is usually not affected.

### Risks

In addition to the risk of an allergic reaction to the local anesthetic, snoring surgery is associated with the following risks:

- Severe pain following the procedure that lasts longer than two to three days. This complication occurs more frequently with LAUP than with somnoplasty or injection snoreplasty.
- Causation or worsening of obstructive sleep apnea. LAUP has been reported to cause OSA in patients who had only primary snoring before the operation.
- Nasal regurgitation. This complication refers to food shooting or leaking through the nose when the patient swallows.
- Dehydration. This complication has been reported with the tongue suspension procedure.
- Permanent change in the quality of the patient's voice.
- Recurrence of primary snoring.

### Normal results

In general, surgical treatment for snoring appears to be most effective in patients whose primary problem is nasal obstruction. The results of snoring surgery depend to a large degree on a good "fit" between the anatomy of a specific patient's airway and the specific procedure performed, as well as on the individual surgeon's skills.

### Morbidity and mortality rates

Mortality rates for UPPP are related to complications of OSA rather than to the procedure itself. With regard to the outpatient procedures for snoring, mortality rates are very close to zero because these surgeries are performed under local anesthesia. Complication rates, however, are high with both UPPP and LAUP. According to one European study, as many as 42% of patients have complications following UPPP, with 14% reporting general dissatisfaction with the results of surgery. Specific complication rates for UPPP are 15% for recurrence of snoring; 13% for nasal regurgitation; 10% for excessive throat secretions; 9% for swallowing problems; and 7% for speech disturbances. Complications for LAUP have been estimated to be 30–40% for recurrence of snoring; 30% for causing or worsening of OSA; 5–10% for persistent nasal regurgitation; 1% for permanent change in vocal quality.

As of early 2003, no morbidity figures have been published for somnoplasty or injection snoreplasty.

### Alternatives

#### *Oral devices and appliances*

Oral appliances are intended to reduce snoring by changing the shape of the oral cavity or preventing the tongue from blocking the airway. There are three basic

### WHO PERFORMS THE PROCEDURE AND WHERE IS IT PERFORMED?

Snoring surgery is done by a head and neck surgeon, a plastic surgeon, or an otolaryngologist, who is a doctor with special training in treating disorders of the ear, nose, and throat. UPPP is performed under general anesthesia and requires an overnight hospital stay. LAUP, somnoplasty, the tongue suspension procedure, and injection snoreplasty are performed as outpatient surgery, usually in a doctor's office or other outpatient facility.

Prosthetic devices to alter the position of the jaw or restrain the tongue during sleep are prescribed and fitted by general dentists or orthodontists.

Polysomnography as a part of a diagnostic workup is done in a special sleep laboratory by experts who are trained in the use of the equipment and interpretation of the results. Advances in technology, however, may allow patients to be monitored at home with portable polysomnographs and a computer with an Internet connection.

types of mouthpieces: those that push the lower jaw forward; those that raise the soft palate; and those that restrain the tongue from falling backward during sleep. To work properly, oral appliances should be fitted by an experienced dentist or orthodontist and checked periodically for proper fit. Their major drawback is a low rate of patient compliance; one German study found that only 30% of patients fitted with these devices were still using them after four years. In addition, oral appliances cannot be used by patients with gum disease, **dental implants**, or teeth that are otherwise in poor condition.

#### *Continuous positive airway pressure (CPAP) devices*

CPAP devices are masks that fit over the nose during sleep and deliver air into the airway under enough pressure to keep the airway open. If used correctly, CPAP devices can be an effective alternative to surgery. Their main drawback is a relatively low rate of patient compliance; the mask must be used every night, and some people feel mildly claustrophobic when using it. In addition, patients are often asked to lose weight or stop smoking while using CPAP, which are lifestyle adjustments that some would rather not make.

## QUESTIONS TO ASK THE DOCTOR

- How often have you performed surgery for primary snoring? Which procedures have you performed most frequently?
- What is your opinion of somnoplasty and injection snoreplasty?
- Am I likely to benefit from lifestyle changes or other less invasive alternatives?
- Should I talk to my dentist about an oral appliance to control snoring?

### Lifestyle changes

Patients who snore only occasionally or who are light snorers may be helped by one or more of the following changes without undergoing surgery:

- Losing weight and getting adequate physical exercise.
- Avoiding tranquilizers, sleeping pills, antihistamines, or alcoholic beverages before bedtime.
- Quitting smoking.
- Sleeping on the side rather than the back. One do-it-yourself device that is sometimes recommended to keep the patient turned on his or her side is a tennis ball placed inside a sock and attached to the back of the pajamas or nightgown. This approach seems to work for some patients with simple snoring.
- Tilting the head of the bed upward about 4 in (10 cm).

### Complementary and alternative (CAM) approaches

There are three forms of alternative treatment that have been shown to be helpful in reducing primary snoring in patients with histories of nasal congestion or swollen tissues in the throat. The first is acupuncture. Treatments for snoring usually focus on acupuncture points on the stomach, arms, and legs associated with the production of excess mucus. Insertion of the acupuncture needles at these points is thought to stimulate the body to release the excess moisture or phlegm.

Homeopathy and aromatherapy also appear to benefit some patients whose snoring is related to colds, allergies, or sore throats. Homeopathic remedies for snoring are available as nose drops and throat sprays as well as the traditional pill formulations. Aromatherapy formulas for snoring typically contain marjoram oil, which may be used alone or combined with lavender and other herbs that clear the nasal passages. Some people find aromatherapy preparations helpful alongside

mainstream treatments because their fragrance is pleasant and relaxing.

## Sphygmomanometer

### Definition

A sphygmomanometer is a device for measuring blood pressure.

### Purpose

The sphygmomanometer is designed to monitor blood pressure by measuring the force of the blood in the heart where the pressure is greatest. This occurs during the contraction of the ventricles, when blood is pumped from the heart to the rest of the body (systolic pressure). The minimal force is also measured. This occurs during the period when the heart is relaxed between beats and pressure is lowest (diastolic pressure).

A sphygmomanometer is used to establish a baseline at a healthcare encounter and on admission to a hospital. Checking blood pressure is also performed to monitor the effectiveness of medication and other methods to control hypertension, and as a diagnostic aid to detect various diseases and abnormalities.

### Description

A sphygmomanometer consists of a hand bulb pump, a unit that displays the blood pressure reading, and an inflatable cuff that is usually wrapped around a person's upper arm. Care should be taken to ensure that the cuff size is appropriate for the person whose blood pressure is being taken. This improves the accuracy of the reading. Children and adults with smaller or larger than average-sized arms require special-sized cuffs appropriate for their needs. A **stethoscope** is also used in conjunction with the sphygmomanometer to hear the blood pressure sounds. Some devices have the stethoscope already built in.

A sphygmomanometer can be used or encountered in a variety of settings:

- home
- hospital

## KEY TERMS

**Aneroid monitor**—A monitor that works without fluids, i.e. without mercury.

**Blood pressure**—The tension of the blood in the arteries, measured in millimeters of mercury (mm Hg) by a sphygmomanometer or by an electronic device.

**Diastolic**—Minimum arterial blood pressure during ventricular relaxation or rest.

**Systolic**—Maximum arterial blood pressure during ventricular contraction.

- primary care clinic or professional office
- ambulance
- dental office
- pharmacy and other retail establishment

There are three types of equipment in common use for monitoring blood pressure.

- A mercury-based unit has a manually inflatable cuff attached by tubing to the unit that is calibrated in millimeters of mercury. During blood pressure measurement, the unit must be kept upright on a flat surface and the gauge read at eye level. Breakage of the unit may cause dangerous mercury contamination and would require specialist removal for disposal. Due to the hazards of mercury, the use of mercury-based sphygmomanometers has declined sharply since 2000.
- An aneroid unit is mercury free and consists of a cuff that can be applied with one hand for self-testing; a stethoscope that is built in or attached; and a valve that inflates and deflates automatically with the data displayed on an easy-to-read gauge that will function in any position. The unit is sensitive and if dropped may require recalibration.
